HUMAN SERUM AS A BLOOD SUBSTITUTE

IN THE TREATMENT OF HEMORRHAGE
AND SHOCK

SIDNEY O. LEVINSON, M.D.

H. OLSON, GRACE LAWRENCE, A.B.,
AND WILLIAM SCRUGGS

The World War afforded an unusual opportunity to study and treat traumatic hemorrhage and shock. This resulted in a great impetus to the use of fluids intravenously for restoring normal fluid balance, combating hemorrhage and resultant shock, and aiding the treatment of wound septicemias and toxemias. At present infusions are also used widely for anemias, burns and dehydration due to various causes. Blood has been the fluid of choice in practically all conditions. However, on reflection it appears that blood may be replaced quite adequately in some circumstances. Thus, in severe infections serum (other than specific serum) may be used instead of blood if there is no associated secondary anemia. Traumatic and operative shock¹ and burns² are characterized by extensive plasma loss and hemoconcentration, resulting in a diminished volume and more viscid blood. It would seem that these conditions would be best relieved by serum or saline solution, which not only reestablish normal blood volume but also reconstitute normal plasma cell ratios. It is still believed that whole blood cannot be replaced in the infusion treatment for anemia, because of the need for red blood cells. It is likewise thought that severe hemorrhage, in which all the constituents of the blood are lost, can be treated only by the restoration of whole blood. Although whole blood is undeniably the ideal restorative fluid, the question may well be raised if it is the only fluid that can be used and if there may not be an adequate substitute which offers advantages over blood.

It may be stated briefly and categorically at this point that the loss of erythrocytes in severe hemorrhage is seldom a vital factor. The sudden and marked diminu-

tion in circulating blood volume is of grave and serious significance because this oligemia leads to rapid development of secondary shock as a result of anoxemia. All this is discussed more fully later. It is mentioned at this time only to bring out the important factors in severe hemorrhage, i.e. oligemia and ensuing secondary shock, and the vital necessity for prompt volume replacement to prevent or overcome the dangerous effects of hemorrhage. It is quite apparent that delay in instituting treatment is a serious matter, for the degree of shock increases and may become profound and irreversible.

All blood transfusions must be preceded by certain laboratory procedures: (1) typing the patient, (2) typing a proper donor, (3) careful testing for compatibility and (4) performing Kahn or similar tests. These procedures are essential in avoiding transfusion reactions and even when rapidly performed consume one or more hours, a delay which may prove fatal in an acute emergency in which the patient needs life restoring fluids immediately. Other fluids, such as dextrose and saline, may be given in the interim, but such interval measures are often ineffective. Hence a serious drawback in the use of blood transfusion as an emergency measure is a certain unavoidable delay of varying duration.³

It was this delay, in addition to other considerations such as frequent difficulty in securing blood for indigent patients, that led to the development and the use of "stored" or "preserved" blood. In an emergency the use of stored blood is an excellent measure, although evidence is accumulating that stored blood is inferior to fresh blood, especially if the storage has been for more than seventy-two hours.⁴ However, even with the use of stored blood there still remains unavoidable delay because of the necessity for typing the patient's blood, performing compatibility tests and filtering the stored blood. In addition, it has been recommended that such blood be administered slowly to decrease unfavorable reactions. For these reasons stored blood does not provide a solution for those emergencies in which prompt blood volume restoration is a vital necessity.

Reactions following blood transfusions are still relatively frequent.⁵ The most serious type of reactions is those due to hemagglutination or hemolysis.⁶ It is clear that although blood transfusion is a valuable measure and often life saving there are two handicaps that restrict its usefulness, i.e. unavoidable delay before

administration and reactions, both due primarily to the corpuscular elements of the blood.

The need for a good blood substitute is quite apparent and has been the subject of much investigation. The ideal substitute should be a fluid which is readily available, is stable over long periods of time, remains in the circulation and is devoid of reactions or ill effects.

Crystalloid solutions have played the most important role to date as blood substitutes. They are readily available, innocuous, economical and easily prepared. However, they are frequently ineffective because under certain conditions they leave the circulation. It was this fact which led to the use of colloidal solutions, such as acacia. Acacia is readily available and remains in the circulation, but its administration is accompanied by reactions and deleterious effects which militate against its use.⁷

The use of serum or plasma infusions for combating the effects of hemorrhage, considered as far back as 1918,⁸ has again been proposed in recent publications.⁹ Serum can be prepared for immediate use and large amounts of pooled serum can be administered without

EXPERIMENTS ON ACUTE HEMORRHAGE

Experiments were performed on anesthetized dogs (pentobarbital sodium) weighing from 13 to 22 Kg., in which blood pressure was recorded in the usual way. A femoral artery was prepared for bleeding and a femoral vein for infusions. After a control blood pressure had been recorded, the animal was bled rapidly until its blood pressure fell to shock level (systolic pressure of 40-60 mm. of mercury). The blood pressure was maintained at shock level for periods varying from ten to twenty minutes before an infusion of either saline solution or dog serum was given. The amount of fluid administered varied from one fourth to several times the amount of blood removed.

Eight such experiments were done, and all of them demonstrated superiority of blood serum over saline solution as an infusion medium following hemorrhage and shock in dogs. The results are best presented by means of protocols on two typical experiments:

EXPERIMENT 3.—Immediate reinfusion. A male dog weighing 21 Kg. was repeatedly bled and given immediate reinfusions until a total of 1,250 cc. of blood had been removed and 1,450 cc.

of saline solution had been administered. The blood pressure was never restored to a normal level (reduced by 30 mm. of mercury) although shock was effectively overcome. The subsequent administration of 200 cc. of serum elevated the blood pressure to its original height (from 110 to 140 mm. of mercury).

EXPERIMENT 7.—Delayed infusion. A male dog weighing 14 Kg., whose blood pressure at 1 p. m. was 146 mm. of mercury, had 425 cc. of blood removed rapidly, the pressure dropping to 40 mm.; at 1:50 the blood pressure was 60 but by 2:30 had fallen to 35 mm. Two hundred cc. of saline solution was then given and the blood pressure rose to 95 but thirty-seven minutes later had

dropped to 40. At 3:07 another 200 cc. of saline solution was infused, elevating the blood pressure to 80, but by 4 o'clock the blood pressure had again fallen to 40 mm. The animal was then given 220 cc. of serum and the pressure rose to 110-120 mm. and remained at this level until the termination of the experiment at 7:10 p. m. (fig. 1).

These experiments demonstrate that immediate infusion with saline solution following hemorrhage produces a moderate degree of recovery, which however is less marked than that following serum infusion. Delay in administering fluids, on the other hand, causes a loss of effectiveness of saline solution, the influence of which on blood pressure is only temporary, in contrast to the sustained effect of serum. Experiment 7 (fig. 1) demonstrates clearly this difference between serum and saline solution when a state of shock has been present for some time. The blood vessels apparently did not retain the crystalloid solution (saline), thereby nullifying the beneficial effects of volume replacement, whereas the colloidal solution (serum) was retained and maintained a normal blood pressure. These results fail to confirm Penfield's¹¹ experience.

Fig. 1 (experiment 7).—Moderate and transient blood pressure elevation following saline infusion in contrast to sustained and marked elevation following serum infusion.

adverse reactions.¹⁰ This study was therefore undertaken to determine whether whole blood could not be replaced effectively by serum and how the latter compared with various crystalloid infusions in the treatment of hemorrhage and resultant shock. The dog was used because its physiologic behavior is similar to that of man in these conditions. Dog plasma forms fibrin clots or "veils" and becomes very cloudy. It was difficult to remove this material, for even after filtration there was a tendency for reformation of the fibrin veil. These fibrin particles and veils resembled the growth from bacterial contamination and required repeated sterility tests. Dog serum instead of plasma was employed, thereby avoiding these difficulties.

HEMORRHAGE AND INFUSION IN
UNANESTHETIZED DOGS

Experimental Procedures.—The procedures are described in detail here because they were used in all further experiments. A considerable section of the right carotid artery was freed and the right jugular vein exposed aseptically under light ether anesthesia. Wide glass cannulas were inserted in both vessels. Three hours was then permitted to elapse to allow the effects of anesthesia to wear off. At the onset of each experiment pulse, respiration and temperature were recorded; blood pressure determinations were made by means of a Tyco anaeroid gage with a small T tube and rubber tubing connected to the carotid cannula on one side and to a citrate pressure bottle on the other. A determination of the circulating blood volume was made by the vital red dye method of Keith, Rowntree and Geraghty as described by Peters and Van Slyke;¹² arterial blood was drawn from the cannulated carotid artery for red blood cell count and hemoglobin as well as for determination of carbon dioxide, oxygen, chlorides, nonprotein nitrogen and plasma proteins. The animal was then bled until it was reduced to a state of shock as judged by blood pressure readings as well as by its clinical condition.

The animal was given infusions through the jugular vein of fluids at body temperature. At the end of each experiment the cannulas were removed, the wounds were dressed and the animal was returned to its cage. In some experiments chemical studies, blood count, hemoglobin and blood volume determinations were done on the following day or subsequently.

RESULTS

Massive Hemorrhage and Delayed Infusion.—Our aim in these experiments was to produce a state of post-hemorrhage shock by a single massive hemorrhage,¹³

leave the animal in this condition for two hours so that increased capillary permeability and secondary shock might develop, and then transfuse with various fluids. It was found that a number of animals recovered to a varying degree in the two hour period, while others remained in shock, and therefore transfusions with saline solution, serum or blood gave varying and inconsistent results. It is worth noting that those dogs having the highest blood pressures at the conclusion of the experiment had received either blood or serum. Another interesting feature was that the blood proteins remained at normal levels following serum infusions, whereas they showed considerable diminution after saline infusion. In one experiment with saline solution

the serum protein level fell to 3.6 per cent per hundred grams, a dangerously low level.

Graded Bleedings.—The method of massive hemorrhage and delayed infusion therapy having failed to produce a consistent and maintained shock simulating the condition frequently encountered in man, we resorted to another approach. A state of shock was induced gradually by repeated periodic bleeding and delayed subsequent infusions. During this process the blood reserves were so depleted that they played a less significant role in recovery and survival. The animals were prepared as described. Observations including pulse rate, respiratory rate, temperature, blood pressure, hematocrit, blood volume, red blood cell count, hemoglobin and chemical blood studies (nonprotein nitrogen, carbon dioxide, oxygen protein) were done at the beginning and at various intervals during the course of the experiments. Thirty per cent of the calculated circulating blood volume¹⁴ was then removed at the rate of 25 cc. per minute. The animal was put aside for

Fig. 2.—Maintenance of good blood pressure levels following blood and serum infusion in contrast to failing blood pressure following saline infusion: 1. Control before experiment. 2a. Immediately following first removal of blood, 30 per cent. 3a. One-half hour after first infusion. 4a. Immediately after first infusion. 5a. One-half hour after first infusion. 2b. half an hour and then given an infusion, allowed to recover for another half hour and bled again. This procedure was repeated periodically until the animal had been bled of 80 per cent¹⁵ of the calculated circulating volume in successive stages of 30, 20, 20 and 10 per cent, and one half hour subsequent to each bleeding the dog was given an infusion of a quantity of fluid approximately equal to the blood previously removed. The amount of fluid infused did not replace the blood withdrawn for chemical studies, red counts and necessary washing out of cannulas (from 150 to 235 cc.)

12. Peters, J. P., and Van Slyke, D. D.: Quantitative Clinical Chemistry, Baltimore, Williams & Wilkins Company 2:706, 1932.

13. The blood removed varied from 2.5 to 4.8 per cent (average 4.0 per cent) of body weight.

14. The literature contains values for blood volume of dogs which vary from 7.5 to 11 per cent of the body weight (Gibson, J. G., 2d; Keeley, J. L., and Pijoan, Michel: The Blood Volume of Normal Dogs, Am. J. Physiol. 121:800 [March] 1938). We arbitrarily chose the figure of 7.5 per cent of body weight as representing the circulating blood volume of the dog.

15. At each successive bleeding fewer red cells were lost, because of dilution from previous infusion. Actual cell volume removed therefore amounted not to 80 per cent but to about 66⅔ per cent of the initial circulating amount.

RESULTS

Twenty-eight experiments were performed. Five dogs were reinfused with their own citrated whole blood removed at preceding bleedings. Twelve animals were reinfused with serum from other dogs. Nine dogs were given saline infusions, four receiving physiologic solution of sodium chloride and five receiving Hartmann's solution, with or without 2 per cent dextrose. Two control experiments were performed in which no restorative fluids were given.¹⁶

TABLE 1.—Mortality Following Hemorrhage and Infusion

Infusion	Number of Experiments	Mortality After				Mortality	
		First Bleeding	Second Bleeding	Third Bleeding	Fourth Bleeding	Total	Per Cent
Control (untreated)....	2	0	1	1	..	2	100
Saline solution.....	4	0	0	1	3	4	100
Lactate (Hartmann's solution).....	5	0	1	2	2	5	100
Serum.....	12	0	0	0	0	0	0
Blood.....	5	0	0	0	0	0	0

Mortality (table 1).—We realized soon that this procedure of graded bleedings was the proper approach to study differences in the effects of the infusion fluids. All dogs that were bled four times, with removal of 80 per cent (30, 20, 20 and 10 per cent) of the calculated circulating blood volume and were given infusions either of whole blood or of blood serum, survived. Dogs given infusions either of saline solution or of Hartmann's solution died during the course of the experiment; one died after the second bleeding (50 per cent), three after the third bleeding (70 per cent), and the remaining five died from ten minutes to two and one-half hours after the second bleeding.

Blood Pressure (fig. 2).—In the beginning of the experiments the control blood pressures of all animals were approximately the same (1, fig. 2); they fell to a varying degree after the first bleeding (2a). A particularly low figure was obtained in a splenectomized dog. Marked variation in response to hemorrhage is to be expected on the basis of varying degrees of vasoconstriction, blood reserves and general condition of the animals. One-half hour after the first bleeding (3a) only seven of the dogs were suffering from various degrees of shock, their blood pressures ranging from 60/35 to 95/65 mm. of mercury. The first infusion was then given and the blood pressure rose to normal levels (4a) in all but four instances. In these, serum had been used and was followed by a "reaction" in which the blood pressure remained the same or was depressed to shock levels. This "reaction" was transient, occurred only after the first infusion of serum, and subsequent infusions of the same lot of serum gave no further unfavorable effect.

All the blood pressures were approximately normal half an hour after the first infusion (5a). From this point on, however, unmistakable differences began to appear between the different groups of animals. The most noticeable drop in blood pressure occurred in the saline animals following the second bleeding (2b). At this time the average blood pressure of the saline infused animals was 84/60, of the serum infused animals 111/83 and of the blood infused animals 118/92. After the half-hour post-bleeding interval (3b) the average blood pressures of the saline dogs was 101/81, of the serum dogs 125/90 and of the blood dogs 127/99. Figure 2

gives a graphic picture of the course of blood pressure as the experiments progressed. In the saline dogs the succeeding bleedings (2c and 2d) were followed by increasingly greater blood pressure drops and correspondingly less marked beneficial effects from the saline infusion. There was also a distinct tendency for the blood pressure to fall during the half hour post infusion recovery phase, an indication that the crystalloid infusion was of only temporary benefit. On the other hand, the serum and whole blood animals maintained good blood pressures throughout the course of the experiment, falling less during bleeding and showing good restorative response following infusion, indicating that serum and blood were retained in the circulation. At the end of the experiments the average blood pressures in those saline animals still alive was at shock levels, whereas the blood pressures of the blood and serum dogs, although reduced from their original levels, were quite satisfactory.

CHEMICAL DETERMINATIONS

Carbon Dioxide (table 2).—The control values for alkali reserve as reflected in arterial blood carbon dioxide was essentially the same in all animals and showed a uniform decrease after the first bleeding, reflecting the effect of the hemorrhage. The succeeding determinations showed a return to normal in the blood and serum dogs. In the five saline dogs that died before the end of the experiments a severe degree of acidosis was found terminally with carbon dioxide values as low as 4.5 volumes per cent. These observations led us to employ lactate saline solution (Hartmann) as an infusion fluid which might combat acidosis because of its buffering capacity. Table 2 shows that no such effect was obtained.

Blood Proteins (table 3).—The serum dogs showed practically no change in blood proteins. The blood dogs showed a definite drop in blood protein. An extreme fall was observed in the saline group, in which the plasma protein values fell from an average of 6.5 per cent to 3.8 per cent, a loss of 42 per cent of the initial

TABLE 2.—Changes in Arterial Carbon Dioxide Content Following Hemorrhage and Infusion

Infusion Fluid	Arterial Carbon Dioxide Content Before			
	First Bleeding	Second Bleeding	Third Bleeding	Fourth Bleeding
Blood.....	56.9	31.3	56.3	34.3
	59.6	33.7	58.1	23.5
	59.4	33.7	52.5	23.2
	37.3	22.1	32.5	25.7
Controls (untreated).....	38.4	25.1		

plasma protein. This decrease is significant, for it indicates that the lost protein was not replaced adequately from the tissue fluids. When the plasma protein falls below a critical level, even normal capillaries become permeable to their contents.¹⁷ Such an effect from lowered plasma proteins is much more marked in an animal which is acidotic and in shock.

Nonprotein Nitrogen.—There was no significant change in the nonprotein nitrogen values in the blood or serum groups, but there was a relative elevation in the saline dogs concomitant with their condition of shock.

Blood Volume.—Plasma volume showed little change in the blood and serum groups. Cell volumes dropped slightly in the blood group, markedly in the serum

16. For the sake of brevity, dogs infused with blood, serum and saline solution respectively are designated as "blood," "serum" and "saline" dogs or groups.

17. Leiter, Louis: Nephrosis, *Medicine* 10: 135 (May) 1931.

group equivalent to the cells removed. The blood volume determinations in the saline group were unsatisfactory, owing to the fact that they were found to be inaccurate and unreliable in the presence of a state of shock.¹⁸

Red Blood Cell Count, Hemoglobin and Hematocrit.—The blood dogs showed a slight decrease at the end of the experiment. Both serum and saline dogs showed very marked falls, the change being more pronounced in the former group, in which it averaged about 50 per cent.

Respiration and Pulse.—Respiration was variable and influenced by unimportant external factors. The final pulse rates in the blood dogs were close to the

TABLE 3.—Changes in Plasma Protein Content Following Hemorrhage and Infusion

Infusion Fluid	Plasma Protein Content Before		
	First Bleeding	Third Bleeding	Fourth Bleeding
Blood.....	6.2	5.4	5.3

Saline solution and lactate.....	6.5	4.2	3.8

original rates. In the serum dogs the pulse rate was somewhat increased, but the saline dogs showed the most consistent and most marked acceleration.

SUMMARY OF EFFECT OF TRANSFUSION FLUIDS

Saline Solution.—The animals derived only partial, temporary and progressively diminishing restorative effects from this fluid. There were progressive fall in blood pressure, increasing acidosis, diminishing plasma protein, diminishing red blood cells and a progressive state of shock terminating in death in all instances.

Serum.—The benefits from this fluid were strikingly good and permanent. Blood pressures were well maintained, alkali reserve and plasma proteins remained normal, shock was effectively combated, and all animals survived. The red blood cells and the hemoglobin were markedly diminished, but no animals showed any serious effects from this anemia and their general condition was surprisingly good at the end of the experiment.

Blood.—This fluid was the best but aside from cell replacement was in most respects not superior to serum. The animals in this group all survived and showed only minor blood pressure decreases and weakness from the prolonged experiment.

LIMITS OF BLEEDING AND INFUSION

We were interested in determining to what extent animals could be bled and reinfused with serum and blood beyond the 80 per cent blood removal and replacement described. Two "whole blood" experiments were performed. In the first animal 140 per cent¹⁵ of the circulating blood volume was removed and reinfused. The final blood pressure was 125/115, compared with an initial pressure of 170/120; the alkali reserve, blood volume and hemoglobin remained relatively constant. The other animal was subjected to 150 per cent blood removal and replacement in stages; the final blood pressure was 125/95, while the original blood pressure had been 170/110. Alkali reserve, blood volume, and so on showed insignificant changes. Both dogs remained in good condition, although somewhat exhausted by the prolonged experiment.

While it is not remarkable that a dog can be repeatedly bled and reinfused with his own blood with complete recovery, the extent to which a dog can be bled when reinfused with blood serum is rather astonishing. Two dogs were bled and infused as usual until 80 per cent of the blood had been removed; then 10 per cent bleedings and reinfusions were continued until 110 per cent and 140 per cent¹⁵ of the blood had been removed before these animals died. Both animals were in fair condition until the last 10 per cent bleeding, following which the blood pressure fell markedly and the animals died before the next infusion period. The hemoglobin was reduced from 118 and 116 per cent to 25 and 24 per cent respectively and the arterial oxygen content fell proportionally; acidosis did not develop until terminally.

Similarly two other dogs were bled and given infusions of serum until 120 per cent¹⁵ of the calculated total blood volume had been removed. In one dog the blood pressure dropped with successive bleedings but rose following the serum infusions. At the end of the experiment the blood pressure was 95/50 and the animal was in fair condition. Hemoglobin fell from 138 per cent to 34 per cent and the pulse rate increased from 88 to 188 beats per minute. Blood carbon dioxide after the 110 per cent bleeding was 37.6 volumes per cent. The other dog had a blood pressure of 145/90 after the fourth infusion and the hemoglobin was reduced from 119 per cent to 63 per cent. The animal withstood four additional bleedings, at the conclusion of which the blood pressure was 115/60 and the hemoglobin 42 per cent. A total of 1,200 cc. of blood had been removed and replaced by an equal quantity of serum. Actually the loss of blood was somewhat higher, approximating a total of more than 1,400 cc. At the start of the experiment the animal's circulating blood volume as measured was 1,057 cc., with plasma volume of 624 cc. and a cell mass of 433 cc. Before the fourth bleeding, after 70 per cent removal of blood, although the plasma volume had remained constant, the cell mass had fallen to 160 cc., about 37 per cent of the original. The circulating cell mass at the conclusion of the experiment was much lower than the latter figure. Yet after such extensive removal of blood and depletion of red blood cells the dog was relatively strong and well, not acidotic and apparently little disturbed by his extreme anemia, for the pulse had increased only from 96 to 142 per minute. This experiment illustrates not only the restorative effect of serum but also the exceptional vitality of some dogs.

REACTIONS

The nature of the serum "reaction" mentioned, which was encountered in about 25 per cent of serum infusions, was of unusual character. The only constant sign of reaction was a moderate and transient drop of blood pressure, from which the animals always recovered spontaneously within the one half hour post infusion period. Further infusions of the same serum into the same animal never brought a repetition of this effect. Occasionally there were additional symptoms, such as chilling, growling, vomiting and defecation, which likewise were of transitory nature and did not recur on subsequent serum infusions. The same pool of serum would cause reactions in one animal and not in others. Compatibilities were performed in all instances, and only compatible serum was used. We were unable to establish a common causative factor, and this subject is now being further investigated with reference to sensitivity and other factors.

¹⁸ Neuwelt, Frank: Blood Volume in Shock, Am. J. Physiol. (Proc.) 126: 593, 1939.

COMMENT

Major attention in the past has been focused on the loss and need for restoration of red blood cells in acute hemorrhage. Rous and Turner,¹⁹ for instance, discarded the plasma and used the red blood cells suspended in Locke's solution. Experimental work and clinical experience by others and ourselves show, however, that a marked and rapid depletion of red blood cells is without fatal effect provided an adequate circulating blood volume and oxygen carrying capacity are maintained. The fatality accompanying or following acute hemorrhage is not due to loss of red cells per se but essentially to volume depletion, resultant inadequate circulation, tissue anoxemia, increased capillary permeability and shock (see Moon²⁰ for literature).

Acute severe hemorrhage produces oligemia, resultant lowered blood pressure and primary shock. The outcome of this primary shock depends on the rate and amount of hemorrhage and the availability of the blood reserves. Blood reserves vary in different animals, depending on their physical condition, and are considerable in the healthy animal. These reserves are mobilized promptly and fairly rapidly when needed; nevertheless, blood may be lost so much faster than mobilization can occur that this lag may prove fatal.²¹ When bleeding occurs slowly, adequate reserves will be mobilized and shock prevented.²²

These physiologic facts are well borne out in clinical experience in man. For example, a patient may have a slowly bleeding peptic ulcer but does not show evidence of shock as long as the blood reserves can compensate for the loss. However, sudden massive hemorrhage from ulcer, ectopic pregnancy or trauma results in oligemia and primary shock. The prime need in this event is to restore fluids and to maintain sufficient circulating blood volume. The actual composition of the fluid is of secondary importance. Hoitink³ has shown that the immediate infusion of large quantities of 0.9 per cent sodium chloride solution was as beneficial in saving the lives of dogs as any other blood substitute which he used, even though there was a profound diluting effect of the saline, reducing the concentration of red blood cells, plasma proteins and the colloid osmotic pressure.

If primary shock and oligemia are not relieved rapidly, tissue anoxemia, increased capillary permeability and acidosis, i. e. secondary shock, follow. Hoitink³ avoided this by immediate restorative measures. Secondary shock following hemorrhage presents an entirely different therapeutic problem than primary shock. Our experience has convinced us that in secondary shock saline solution is not the life saving fluid that it proves to be in primary shock because capillary permeability is increased. The experiments on anesthetized dogs demonstrated clearly that in secondary shock saline solution produced only moderate and transient elevation of blood pressure. Serum, on the other hand, produced a marked and sustained elevation of the blood pressure, indicating that the infused serum was retained in the circulation (fig. 1).

The experiments with graded hemorrhage and delayed infusion provided a method for demonstrating the striking difference between the value of crystalloid solutions and serum. The initial bleeding and the delay of reinfusion caused a slightly increased capillary permeability, permitting escape of the infused crystalloid solution. As successive bleedings were performed, capillary permeability in the saline infused animals increased progressively, with greater loss of the infused saline or dextrose solution and progressively diminishing circulating blood volume. In the serum dogs the capillary permeability was not sufficient to allow for escape of the infused serum, which remained in the circulation and maintained adequate plasma volume. Furthermore, while serum contains practically all plasma proteins, crystalloid solutions caused a dilution of plasma proteins with resultant lowering of the colloid osmotic pressure of the blood and transudation of saline solution into the tissues.^{22a}

Although whole blood is the best restorative fluid in massive hemorrhage, its use always entails an unavoidable delay which may be fatal. There is also the possibility of reactions despite the most scrupulous care. Furthermore, owing to the difficulty in obtaining donors, it is not customary to give quantities of blood larger than 1,000 cc. (except with the use of stored blood) despite the fact that the degree of hemorrhage may be sufficiently severe to warrant from two to three times this quantity.

Our experiments have demonstrated that serum overcomes all the effects of hemorrhage in dogs except the loss of red blood cells (this loss, as we have seen, may be quite extensive without serious effects). There are many practical advantages in the use of serum as a blood substitute. It may be prepared,²³ tested and stored in large quantities for long periods of time without deterioration. There is no need for any antibacterial preservative if the serum is carefully prepared under aseptic conditions and properly sealed against contamination. Pooling of serum partially suppresses the iso-agglutinins and there is further inhibition of iso-agglutinins by the patient's blood.¹⁰ Therefore, pooled serum may be given without any regard for blood groups and does not require preliminary typing and compatibility. This allows serum to be administered without delay. Serum after proper preparation requires no particular care (refrigeration temperatures for antibody preservation are of no concern), may be transported easily and can be handled and injected as simply as saline solution. If serum transfusion should prove to be as effective in treating hemorrhage and subsequent shock in man as it appears to be in the dog, it would be a valuable and effective blood substitute. The advantages enumerated, principally those of immediate availability and innocuousness, recommend its use. It overcomes all the effects of hemorrhage except the loss of red blood cells; it is obvious that this loss, when sufficiently great, requires ultimate replacement by whole blood. The use of serum, however, as an interval therapy, should prevent the development of shock. It should remove the need for "emergency" transfusions and the necessity for hasty blood typing and compatibility tests. Serum transfusions as an immediate and interval therapy should prevent or combat oligemia, shock, acidosis and the like, so that if blood is subse-

23. Those institutions which have established "blood banks" may use the plasma from older, unused blood instead of discarding it.

quently administered it will be given to overcome secondary anemia rather than to treat the shock and collapse that is customarily encountered following massive hemorrhage. Furthermore, the necessary surgical treatment for the primary cause of hemorrhage may be instituted more promptly and is attended by more success when the patient is rapidly relieved from shock and is in good general condition.

There is urgent need for an effective blood substitute. Even in large hospitals and in large cities where blood can be secured with relative promptness there are situations in which immediate availability and injection of a good blood substitute would improve the therapy and enhance the prognosis. A greater need for a blood substitute exists in small institutions and small centers of population where there is greater delay and more difficulty in performing blood transfusions. Sterile flasks of serum could be kept on hand for an indefinite time and the serum could be promptly administered when a situation arises in which transfusion is urgently needed.

There were many publications and much research during and following the World War on the subject of blood substitutes because of the great need for such material at the battle front. Saline solution and acacia were used commonly although they were not satisfactory. Preserved red blood cells²⁴ were employed in a very limited way. "Preserved" or "refrigerated" blood rendered valuable service during the recent civil war in Spain, and this substitute for fresh blood is receiving prominent consideration²⁵ by the countries engaged in warfare at present. There are many drawbacks inherent in the use of refrigerated blood under front line conditions: the limited time blood can be kept before deterioration, the necessity for rapid transportation at refrigerator temperature, the necessity for care in transportation to minimize erythrocyte destruction from shaking, and lastly the necessity for typing and compatibility tests (unless only group O blood is used).

If serum is as effective in overcoming the effects of hemorrhage in man as it appears to be in dogs, then certainly it would provide the ideal substitute at the battle front. Since serum requires no particular care in handling and no preliminary testing and may be preserved for a long time, it can be processed in ample quantities from the blood of noncombatants in civilian centers far removed from the war front, prepared in proper containers ready for use and distributed directly to the front, where it can be stored until used. A wounded person who has lost much blood or is in shock can receive an injection of serum at a first aid station before he is transported to the base hospital, at which place, additional serum (or blood) can be administered. There is reason to believe from our experiments that such means, allowing for prompt volume restoration with a fluid retained in the circulation, would be a great factor in decreasing shock and mortality from wound trauma and hemorrhage. We have had the opportunity to employ pooled human serum in a limited number of cases of hemorrhage or shock. The effects from immediate human serum infusion on the blood pressure and general condition in these cases paralleled the beneficial results observed in our animal experiments. We expect to continue and amplify these clinical studies on human beings and we hope that others

will find this subject of sufficient interest and value to employ serum transfusions and to observe and report their results.

SUMMARY

1. Immediate restoration of fluid volume following extensive hemorrhage prevents the development of secondary shock.

2. Delay in restoration of fluid volume following extensive hemorrhage permits the development of secondary shock.

3. Crystalloid solutions are ineffective when secondary shock develops after severe hemorrhage.

4. Serum is an effective agent in combating all the effects of severe hemorrhage and resultant secondary shock except the loss of red blood cells.

5. Erythrocyte loss is not serious unless very extensive.

6. Whole blood, the best restorative agent, requires time consuming laboratory tests preliminary to administration, leading to an unavoidable delay counteracting its ultimate beneficial effects.

7. Serum may be given in massive amounts without any delay or preliminary testing.

8. Serum can be used as an interval measure preceding blood transfusions or as a substitute measure when blood is not available or when erythrocyte loss is not too extensive.

9. Human serum, as a blood substitute, should find wide use not only in civil emergencies but particularly in time of war at the battle front.

PRESENT DAY CONCEPTS OF CONVALESCENT CARE

I. OGDEN WOODRUFF, M.D.

Director of the First Medical Division of Bellevue Hospital
NEW YORK

Realizing the importance of convalescent care and the necessity both of bringing this importance to the minds of the medical profession and of improving the quality of the small amount of institutional convalescent care available, the Public Health Committee of the New York Academy of Medicine formulated and published in 1925 a set of standards for convalescent care. A recent review of these standards brought about the realization that certain advances in knowledge of nutrition and of the adverse influence of various psychosomatic disturbances on restoration to health warranted a renewed study of the whole subject of convalescent care.

A two day symposium on the problem of convalescent care was held at the New York Academy of Medicine Nov. 9 and 10, 1939, under the joint auspices of the Committee on Public Health Relations of the academy and the Josiah Macy Jr. Foundation. At this conference some twenty papers were presented by distinguished physicians dealing both with the broad problems of convalescent care and with the special needs of patients recovering from particular illnesses.

My purpose in this paper is to organize and present this wealth of material so as to bring out in a relatively small compass the important points emphasized, and in the light of the information obtained to outline some program for the future.

25. Use of Refrigerated Blood for Armies, Paris letter, *J. A. M. A.* 111: 1311 (Oct. 1) 1938.

The papers referred to in the footnotes are to be published by the New York Academy of Medicine in the Proceedings of the Conference on Convalescent Care.

Read before the Conference on Convalescent Care at the New York Academy of Medicine under the auspices of its Committee on Public Health Relations, Nov. 10, 1939.

THE PATIENT AS AN INDIVIDUAL PROBLEM

First, to touch on the inadequacies of the present situation, one may say that practically nowhere are the standards formulated fifteen years ago met at the present time. To put it tersely, the consensus at the conference was that in this country at least we are doing but little in the way of organized convalescent care and what we are doing we are doing, for the most part, very badly.

There are about 8,000 beds for convalescent care throughout the entire country. Four thousand of these are in the New York City metropolitan district, which leaves only 4,000 for more than 120,000,000 people.

The chief responsibility for the inadequacy of facilities and for the inadequacy of standards of convalescent care rests squarely on the medical profession.

It is a severe indictment of our profession that we as physicians, and particularly those of us who have the benefit of hospital practice and experience, are much more interested in disease than in patients. Adequate convalescent care requires interest in the needs of a patient as a person; we are interested in the patient as a case. The very phrase that interns use (and one rarely criticized) that "here is an interesting case of heart disease" rather than "here is a patient with an interesting heart disease" supports this point.

I admit that in large urban centers there may be some slight justification for this attitude. In large hospitals, particularly those with rapid turnover of patients, where most of the visiting staff do voluntary duty, there are so many pressing medical problems in connection with the large number of patients under their care that little time is left after attending to these needs for concern over the apparently secondary factors of after-care and the restoration of the patient to health, together with an inquiry into whether the environmental conditions to which the patient returns are conducive to the maintenance of health.

The knowledge that in such a vast majority of instances these environmental factors are hopeless of correction, and the lack of sufficient personnel in the social service department of many hospitals to make more than a few routine inquiries, bring an attitude of defeatism about doing much for the patient after discharge from the hospital. Yet the fact remains that disease, rather than the patient, is still the primary interest of most physicians, and one of the points most emphasized and reemphasized in the round table discussions was that no satisfactory results in convalescent care will be secured until there is general acceptance as a fundamental principle of the idea that in convalescent care attention must be focused on the patient as a person who has been ill and is recovering strength and has particular and individual problems to be considered in his course to recovery.

NUTRITION AND CONVALESCENCE

Another reason why even in our limited number of convalescent institutions we fail to do our best for these patients is that we still look on this period as one which presents merely an opportunity to obtain a rest interval before returning to home and work, and in which rest and diet are to a great extent carried out in a purely routine manner.

This is largely due to the fact that in the convalescent care, and even in the hospital care of many of our patients, we have failed to put into practical use the great increase in our knowledge during the past fifteen years in the field of nutrition and nutritive disturbances.

In his presentation, Dr. Kruse¹ has reviewed the tremendous increase during this period in our knowledge of the nutritive needs of the human being and of the various clinical syndromes which have been recognized as due to nutritive inadequacies of one or more essential factors, particularly in diet. It has become possible to postulate and determine a basic diet which will contain the essential elements in sufficient quantities of vitamins and minerals, apart from caloric requirements, necessary to produce a state of nutritive balance for an individual of given size, age and activity. Frequently, especially in the low-income group and in various diseases, the diet of the patient prior to his entering the hospital falls short of containing the minimum amount of the required essentials, so that the patient frequently arrives for treatment in a condition of nutritive inadequacy even though it be in a subclinical state. A further drain on nutrition may be produced by an episode of acute illness, during which frequently in the hospital no attempt is made to meet the nutritive requirements of the individual in respect to his particular disease process and his previous dietary inadequacy. Finally, in convalescence we usually place our patient on a routine diet which in no way takes into consideration his nutritive needs in respect to his previous dietary inadequacy or the nutritive depletion of his illness and then send him back in a state of serious negative nutritive imbalance to his home, where his diet may again be insufficient for his basic requirements.

In other words, in our convalescent homes we are still labeling our diets as "regular diet," "soft" or "solid diet" (according to their physical characteristics) or "cardiac diet" or "nephritic diet" or "convalescent ulcer diet" or "colitis diet," according to the disease from which the patient is convalescent, without any thought as to whether any of these diets are adequate to repair the nutritive deficiencies from which this or that individual patient may be suffering.

Again here you see the new thought in convalescent care, that the especial needs of the particular individual who is seeking to regain health, rather than the convalescent care of a case of pneumonia, or rheumatic fever, or appendicitis, is the thing of paramount importance.

PHYSIOLOGY AND PSYCHOLOGY OF CONVALESCENCE

Dr. Pepper,² in a paper covering the general problems of convalescence, regards the medical neglect of the convalescent state as due to the attitude, generally prevalent over many years, of attributing many remote phenomena of convalescence to psychologic causes. He challenges this as a theory accepted without sufficient supporting proof and states that the time has come to investigate the convalescent state scientifically to endeavor to discover whatever bodily or physical causes there may be for the phenomena of convalescence. The "convalescent state" is fallaciously assumed to be a single entity, produced by a common cause, exhibiting common phenomena and amenable to common management. In convalescence he declares, again emphasizing the need of studying the problem of the individual, that no two diseases—and I would add that frequently no two patients ill with the same disease—can possibly have the same state of bodily and psychologic conditions after the illness subsides and convalescence begins.

Certain diseases are known to produce physiologic and biochemical shifts from normal, and in a few dis-

1. Kruse, H. D.: *Results of Recent Research in Nutrition*, with Particular Reference to the Convalescent State.

2. Pepper, O. H. Perry: *The Physiology and Psychology of Convalescence*.

eases we know that this abnormality persists even after the acute phase of the illness has disappeared. This knowledge should challenge the medical profession to further study in other illnesses to ascertain whether there may not be much more evidence of disturbed physiologic, biochemical and nutritive processes in the convalescent state than has previously been suspected.

Even should we accept the fact, as some psychiatrists maintain, that a large proportion of the phenomena of convalescence arise in the mind rather than in the body, it may well be that many of these disturbances of psychology are dependent primarily on bodily dysfunctions.

It seems to me that this point of view is worthy of most careful consideration and respect. We know that the hyperthyroid patient is prone to psychologic and emotional imbalance; the diabetic patient in insulin shock can undergo the most profound personality disturbances; the exhaustion of childbirth, following the metabolic changes of pregnancy, may suddenly cause serious mental illness; physical and mental depression so often follow grip, and many patients at the onset of an acute illness are thrown into such an acute mental disorder that they are admitted to a psychiatric service, where only after examination their underlying illness is for the first time recognized. Moreover, psychic disturbances, after shock, trauma, and surgical operations, are well known.

Certainly, at any rate, if in convalescence there are persistent deviations from normal in metabolism, nutrition, body chemistry and physiology, restoration to health may well be expedited if attention is directed to correcting these abnormalities; and, again in this connection stressing the importance of the individual, not until we learn to recognize in each convalescent the actual abnormalities which persist from the preceding illness, and which differentiate that individual in convalescence from his condition in health, can we meet properly the therapeutic indications in his particular case.

PSYCHOSOMATIC FACTORS

From this discussion it is a natural transition to the consideration of the psychosomatic problems of convalescence presented by Dr. Robinson.³ By this time I am sure that the psychiatrists are saying to themselves "True, all these psychologic conditions you have touched on may be brought about by organic illness or disturbed somatic functions, but we say that they have occurred because these individuals have some psychologic or emotional dysfunction or maladjustment which has made them react in this particular manner." Well, I am not denying this, though to my mind objective proof sustaining this contention may be difficult to adduce; and while I maintain that every effort should be made to restore the normal physiologic, biochemical and nutritional balance in the individual during convalescence, I also willingly grant the desirability of exploring the question of the existence of psychologic factors in each convalescent patient which may retard recovery and of initiating steps which may resolve these problems.

The practical question immediately arises as to how much can be accomplished in the field of psychotherapy in the limited period of institutional convalescent care, even allowing for a much greater elasticity in the duration of stay of particular individuals than is permitted at present.

Dr. Robinson does admit that the psychosomatic disorders of the patient as a person may be given rather

scanty consideration during an acute illness and its convalescence, but he emphasizes that in chronic illness great attention must be paid to these factors. He makes a distinct contribution in showing the need of attacking these problems of psychologic disturbance as they arise in the course of chronic illness, a phase of treatment now greatly neglected. Where they are found in patients with chronic illness in convalescent institutions, they increase the duration of convalescence necessary to bring about a satisfactory adjustment. Also in this particular type of patient there arises the danger of increasing the patient's already strong feeling of willing dependence on the world in general and his resistance against facing life and developing a proper sense of personal responsibility. One other very important point made was that, after acute illness, convalescent care of a type which really restores the patient to health may well prevent the development of psychosomatic disorders which would be problems in later illnesses. Finally, the need was stressed of providing convalescent aid for the private patient of small means whose need for maintaining financial solvency frequently drives him to the resumption of his full activities all too early, and who is under much greater mental strain in his illness, as a result of anxiety over his expenses and possible loss of his job, than is the indigent patient in the hospital ward.

NEGLECTED OPPORTUNITIES

In the trend of this discussion there must have come to the minds of many still other opportunities heretofore neglected in convalescent care.

The first of these is the opportunity for the discovery and adjustment of environmental factors and family situations which may have contributed to the occurrence of the patient's illness and which may be militating factors against the preservation of health, once recovery is attained and the patient is back in his usual milieu. This is particularly useful for patients showing psychosomatic disorders, and emphasis is laid on the necessity of getting the cooperation of the relatives in helping the patient back to health.

Information having bearing on these conditions may have been obtained by the department of social service at the hospital during the patient's illness but only rarely are the results available to the authorities in the convalescent home. Too often nothing is attempted to alter these conditions for the benefit of the patient, and frankly all too frequently economic factors prevent the remedy of serious handicaps.

The fact remains, however, that at present in only a few instances are there two organizations, the hospital and the convalescent home, which are conjointly interested in the restoration of the individual to health, taking any cooperative measures to remedy conditions which may have been remote factors in the development of disease processes in an individual and which if uncorrected may continue to exert their baneful influence in undermining the health to which he has been restored.

The second opportunity is that of helping the patient during this period of rest and relaxation to evaluate himself, to take account of stock, to consider his habits of life and work in relation to their effect on his health, to judge whether both ends of the candle of life have been burning, and to determine whether certain dominating ambitions and tendencies are sufficiently important to strive for when measured against the nervous and bodily toll exacted; an opportunity to help him to

3. Robinson, G. Canby: Psychosomatic Factors in Convalescence.

develop a new philosophy and habit of life and work compatible with the reserves which age and illness have left him.

Unfortunately, in many of our convalescent groups it will be a case of "needs must when the devil drives"; but, even so, in general there is a golden opportunity here for sound work in health education which so far has been almost completely neglected.

So much then for what the conference has brought to our notice of the broader medical opportunities and requirements of convalescent care, together with the obvious deficiencies (apart from actual bed facilities) which at present exist.

SPECIAL NEEDS OF PATIENTS

Concurrent with these are the obvious recommendations which I shall briefly summarize at the end of my presentation, but before proceeding to that let us survey the special needs of patients suffering from certain types of disease and the general sense of the conference respecting these. Those which have been included for special consideration are the sufferers from cardiac diseases, renal disorders and infection of the urinary tract, gastrointestinal and respiratory ailments, cancer, postoperative hyperthyroid states, psychiatric disturbances, certain neurologic diseases, certain surgical operations and orthopedic conditions, as well as the recently delivered mother. There are also special requirements for children and the aged.

Obviously, to present the needs of any of these special groups in detail would take much more space than is available here. The outstanding fact disclosed in the discussion is that with the exception of the provision of convalescent care for patients with heart disease (and this to a very limited degree) none of the facilities available meet the medical problems involved; and here may be interpolated the interesting observation that in only one convalescent home serving New York City (that for cardiac children) is any scientific study being conducted to evaluate the efficacy of the methods employed.

In the opinion of the leaders in these fields, only by providing convalescent care in the setup of a convalescent hospital can the hope be entertained of restoring many of these patients to a reasonable state of health. This holds especially for most patients convalescent from the exacerbations of chronic illness, whose needs have been discussed by Dr. Boas,⁴ and presents a serious economic problem but one which must be faced and solved if we do not purpose to continue in the performance of pious gestures.

The psychiatric patient, for his cure, requires a prolonged stay in the sheltering atmosphere of a convalescent institution of the home type with expert psychiatric and nursing guidance. Thence he can make attempts at contact with the outside world, increasing the duration of these as his confidence and ability to adjust himself return, and thus lessening the likelihood of the repeated breaks to which many of these patients are subject.

Many neurologic and orthopedic patients can be restored to a fair degree of practical efficiency only by a prolonged period of care in an institution providing elaborate types of physical therapy carried out by competent technicians under expert medical supervision. A knowledge by physicians of the use of these modalities and of their potentiality when properly applied is all too rare today. With a knowledge of the results which

can be obtained in private practice in cases of hemiplegia, one can only speculate on how many helpless invalids with this disease who are now filling our wards might have been restored to a fair degree of functional efficiency by the employment of proper physical therapeutic measures earlier in the course of their disorder.

Patients suffering from renal disorders and other diseases and infections of the urinary tract are to be included among those who, in the opinion of Dr. McCann,⁵ need care in the convalescent hospital as opposed to the convalescent home. He stresses one important point in respect to infections of the urinary tract—namely, that these infections tend toward a state of latent chronicity, that the treatment in the hospital simply disposes of the acute exacerbation, and that in order to prevent relapse and recurrent hospital visits it is necessary to achieve sterilization of the urinary tract. This should be carried out during the period of convalescence and for its accomplishment requires the setup of complete urologic clinics and expert supervision such as can be obtained only under hospital conditions.

Discussion of the convalescent care of sufferers from prior hyperthyroidism and gastrointestinal disturbance emphasized the desirability of careful consideration and treatment of emotional and psychologic disorders which either were obviously manifest or else were potent factors in causing exacerbation of existing illness to the point of requiring hospitalization.

The necessity of obtaining satisfactory special diets in convalescence (at present not available) for sufferers from gastrointestinal disorders and the need of building up post-thyroidectomy patients were dwelt on, but nowhere did I note any special preoccupation with or interest in the fundamental nutritional needs or deficiencies of individuals convalescent from these various disorders, or any suggestion as how to cope with these problems as they arise in individual cases.

The newly delivered woman is at present greatly neglected. Although it is well known that the normal involution of parturient organs takes at least eight weeks, most women are forced to resume the burden of household cares within two weeks of their delivery. Of the slender opportunities available for giving them help during this period, not one is satisfactory. The home which receives the mother alone is entirely unsatisfactory except for the woman who cannot nurse her child, as it means compulsory weaning. Homes which take both mother and infant present the grave danger of nursery cross infection unless nursing techniques, professional standards and supervision are so high as to be prohibitive in cost. Furthermore, few mothers will be found willing to leave their families for this additional period. For this reason housekeeping aides are needed, but their training at present is inadequate. However, the potential possibilities in this form of assistance are great, and economically it is the cheapest form of aid. Apart from the practical means of easing the mother back gradually into full family responsibilities, unrivaled opportunities exist for instruction in household management, dietetics, cooking technique, child care. In brief, here is an opportunity for extensive health education as applied to a family unit.

No point of view of convalescent care for the mother is satisfactory which does not take into account health of the infant as well. No one thing probably contributes so certainly to the maintenance of her

4. Boas, Ernst P.: *Convalescence and Chronic Illness*.

5. McCann, William S.: *Convalescent Hospital Care of Patients Diseases of the Kidneys and Urinary Passages*.

in the first few months of an infant's life as breast feeding. Much more should be done at present in encouraging mothers to wish to nurse their infants for expediting the involution of their own pelvic organs, for the infant's physical condition and, as Dr. Powers⁶ points out, for establishing a proper emotional relationship between child and mother. Much more should be done to educate the mother in the value of nursing in promoting this relationship and how after leaving the hospital she may so live and eat as to insure an adequate supply of her own milk.

One of the discussions which showed an important and salutary advance in thought was that on the broad question of institutional convalescent care for surgical patients. Dr. Ravdin⁷ says that no longer is the operation considered "the major part of surgical therapeutics." What a far cry from the days of my own internship, when frequently the first introduction of the operating surgeon to the patient was when he saw him anesthetized on the operating table and incised him to see whether the house surgeon's diagnosis was correct. Dr. Ravdin's thought follows so closely the trend of those which I have been unfolding, and he expresses it so well, that I feel that it can best be presented in his own language:

The patient with a gastric ulcer becomes John Jones who has a gastric ulcer. Each patient before and after operation becomes an individual problem, and this provides a closer relationship between the surgeon and his associates and the patient.

Again, listen to this:

The past emphasis on the economic values of convalescent care naturally had as its outcome a lack of intelligent interest in the planning of the institution for convalescence, and there are few quantitative studies available from which we may draw information as to the value of such care and the type of organization most suited to provide transitional medical and surgical treatment. It is to be hoped that this conference may bring forward for discussion the requirements from the medical and surgical points of view and point out the value of carefully controlled studies during the convalescent period.

Another practical and worth-while suggestion which the surgeons made was that of utilizing convalescent institutions for preoperative treatment of persons who need building up into a state of nutritive balance—a sort of convalescence-in-reverse process which would improve operative results and shorten the postoperative convalescent period.

There is a generally growing feeling that in order adequately to restore back to health patients who present difficult problems requiring special apparatus and technics and for whom convalescent care will be prolonged it will be necessary to develop institutions in which there will be a close and even interlocking relationship between the professional staffs of the hospital and the convalescent institution to which the patients are referred.

I regret that the lack of a background of practical clinical experience in the field of pediatrics renders me unable to summarize Dr. Nelson's⁸ paper with the insight and interpretative ability it deserves. One may say, however, that in the case of children convalescing from various types of disease one faces the same need of special facilities, technics and equipment as in that of adults. For others who require more simple care the foster home has not been sufficiently utilized.

Dr. Nelson pointed out that so-called malnutrition cases (most of which were considered environmental in origin) did not hold gains made in convalescent institutions and that a feeling against accepting them was growing. In the discussion it was brought out that in one institution the inauguration of a home visiting nurse service to educate the parents of these children in their dietary needs and in proper selection of their food was found to produce a marked decrease in the incidence of relapse.

At the other end of the life span Dr. Lewellys F. Barker,⁹ who presented the needs of the aged and the special problems arising in their convalescent care, lays emphasis on the increasing importance of the convalescent care of the aged by indicating that in 1930 there were in this country about 12,000,000 children under 5 years of age and some 6,500,000 individuals over 65 years of age. However, with the diminishing birth rate and the prolongation of the life span it is probable that by 1975 there will not be more than 6,500,000 children of the age group just mentioned but there may be 30,000,000 individuals over the age of 60 and some 22,000,000 over the age of 65. This emphasis is particularly made with reference to the fact that even now, with our relatively small number of beds for convalescent patients, a considerable proportion of them are exclusively for children. He calls attention to the marked nutritional deficiencies in aged convalescents, vitamin, mineral and hormone, as well as actual impairment of body weight. These individuals with depleted reserve powers, lowered processes of assimilation, sluggish bodily response and the difficulty often of inducing an adequate food intake make the problem of rebuilding extraordinarily difficult. Added to this is the fact that few physicians are expert or even interested in geriatrics.

There are further difficulties encountered on the side of personality in handling older people; they are apt to be "crochety"; they have fixed habits, dislike change and often are childishly unreasonable. People in this age group are more apt to make satisfactory progress if segregated in convalescent wards or homes than when cared for in mixed age groups. He also feels that the younger group in the profession may not be so readily able to understand and handle these individuals as those with greater maturity and experience and riper judgment. This impression does not coincide with my own observation and experience. I agree that the young are often intolerant of the aged in their own home circle, but I think that old people frequently prefer having young physicians take care of them. They find them willing to give more time and to be less impatient with their whims and vagaries and prolixities. They feel that they are important and can boss the young doctor, who usually gains his point by circumvention or wheedling, a time-consuming process which the busy physician's practice does not permit. He also brings out one excellent point, and one which is very important for relatives of aged patients to recognize. After an episode of illness they should not be wrapped in cotton wool, hedged with restrictions and deprived of independence. Every effort should be made to keep them interested in life and with a feeling of importance in their new circle. Nothing hastens the aging process or causes a faster disintegration of personality than the feeling that one's usefulness is past and that one is ready for the junk pile.

7. Ravdin, I. S.: Institutional Convalescent Care for Surgical Patients.

8. Nelson, Waldo E.: The Convalescent Care of Children.

9. Barker, Lewellys F.: Convalescence of Old-Age Patients.

These then are the more important general and special problems which were brought to light during the conference. In parading these skeleton facts I hope that at least some of the shreds of the spirit of the conference which clothed them may be conveyed by means of this summary.

FURTHER QUESTIONS

The next questions are what to do, where to go, how to plan. The burden of responsibility for formulating the answers to these questions should be laid on the table of another conference, and I am sure that it will take more than one such conference before practical working agreements are reached. As an ultimate goal one may offer the following. It will be reached only after a period of many years, during which we shall have to put up with many expedients and makeshifts as we change our objective.

Apart from the quantitative increase in facilities which ultimately will be provided, we must face the fact that to accomplish the ends we are seeking we also ultimately, with few exceptions, must scrap completely the type of organization under which our convalescent institutions at present operate.

We must face the fact that to restore these patients to health we cannot depend on their casual supervision by a general practitioner in the neighborhood. We cannot let the choice of a matron-in-charge depend on the financial embarrassment of some widowed gentlewoman who is a social acquaintance of wealthy members on the board of trustees.

Each institution should have a full-time medical head, free from administrative duties, well grounded in the new knowledge of the biochemical, physiologic and nutritive disturbances which occur in illness and persist in convalescence. In addition he should have a fair understanding of the psychologic disturbances which his patient may show, and some knowledge of the techniques for the correction of these.

If such a paragon does not exist we shall have to develop him or, more likely, we may find that we shall have to have a second physician who will devote himself exclusively to the psychologic problems of the individual patient. These two men should not be so narrowly trained that their points of view are mutually antagonistic, a condition of mind today which is rather prevalent. In addition an expert dietitian trained in the modern knowledge of nutritive requirements is necessary, as well as nursing personnel, the type and number of which will be determined by the types of disease which the institution receives.

This implies an overhead expenditure which will not justify a bed capacity below a certain minimum, which will be gradually determined by experience.

In order to apply our more recent knowledge for the benefit of the convalescent patient, convalescent homes will have to receive from hospitals regarding all patients referred much more detailed reports as to their medical condition on discharge and also medical social workers' reports, which will stress those economic and environmental factors which may have been predisposing causes for their breakdown and which may militate against health maintenance when the patients return home. In connection with this it is interesting to note that the reference cards now in use in New York City contain the large space of one and a half lines for all medical and social information.

Gradually there should be developed more and more convalescent institutions, offering facilities usually found only in a hospital, for a clinical check-up on

patients recovering from certain types of disease and in these institutions also must be installed considerable equipment, especially in the field of physical therapy. This, of course, presupposes the inclusion in the personnel of technicians capable of handling these modalities and a medical man with a knowledge of their indications.

Eventually, I can also foresee that the realization will come that for patients recuperating from certain diseases a close interrelationship between the hospital and the convalescent institution will be found desirable and that members of the attending hospital staff will receive periodic assignments to duty at the convalescent institution. It is interesting to note that in a few instances this is already an accomplished fact.

In view of this possibility, the location of convalescent institutions in respect to their distance from hospitals must be given consideration. With the realization that other factors in the treatment of convalescence may be as important as rest, fresh air and sunshine, a plan recently developed by Commissioner Goldwater may present great potentialities. He has planned to convert the roofs of two of the tuberculosis hospitals now under construction into day camps where patients after their discharge may return to spend the day for periods to be determined by the hospital staff. The possibility of extending this form of convalescent care to other types of patients in other hospitals, where practical, might provide at minimum expense a satisfactory setup for patients still in need of hospital facilities for investigation and treatment where they would be under daily supervision by the same hospital staff as they were during the acute phase of their illness.

Convalescent care for the recently delivered woman should be broadened. The housekeeper service should be greatly extended and some plan should be evolved, in connection with this service, whereby these activities may be used as a demonstration to the mother and family of how to carry out household duties more efficiently and economically, and whereby during this period they may be fitted into a program of health education for the family unit.

Finally, if we are not to go blundering on, certain convalescent institutions should be selected as experimental stations in which, through study, we may increase our knowledge concerning the biochemical, physiologic, nutritive and psychosomatic problems of the convalescent state. In these institutions, scientifically controlled methods of treatment should be evaluated by careful analysis of the results obtained.

This field is practically unexplored. The time necessary for such investigation to be of proved value would cover a period of years, and the cost would be considerable. To finance such studies would be one of the greatest contributions to health preservation and disease prevention that foundations could make.

The program just presented is idealistic, but unless we strive for the ideal we shall remain glued in the morass in which we have been fixed these many years. If the type of convalescent care advocated is deemed unpractical, it is largely because of its economic implications. However, which is the more expensive, hospital care or convalescent care? Don't we admit that a lot of hospitalization results from failure to restore patients to health after previous illness? Isn't it likely that with more convalescent care of the right kind less hospital care will eventually result? What will be the balance of expenditure between the two? Who knows? There may be no total increase.

But with a setup of convalescent care which is sound medically and which we feel sure will accomplish what convalescent care is supposed to accomplish and which it now fails to do, and which will cause a broad increase in health and the happiness of living, who can say that it is utopian? In the light of our present vast expenditures on human suffering, should we not strive for this ideal, through which, by handling our problems of convalescence in an intelligent and scientific manner, much of this human suffering may be prevented and much of the expenditure for it eliminated?

AORTIC REGURGITATION AND MITRAL STENOSIS IN A MARATHON RUNNER

WITH SPECIAL REFERENCE TO THE EFFECTS OF VALVULAR HEART DISEASE ON PHYSICAL EFFICIENCY

ERNST JOKL, M.D.

Head of the Department of Physical Education
AND

M. M. SUZMAN, M.D.

Lecturer in Clinical Physiology; Assistant Physician, Johannesburg General Hospital

JOHANNESBURG, SOUTH AFRICA

At the compulsory medical examination of competitors in the marathon race at the Royal Scottish Gathering in Johannesburg, South Africa, in 1935, competitor G. M., aged 32, was found on cursory examination to have both systolic and diastolic murmurs over the apex and base of the heart and a diffuse and markedly forcible impulse.

It appeared to us that these abnormalities constituted sufficient reason to advise him against participation in the race. He stated, however, that as he had competed in similar races on many occasions in the past without ill effects he saw no reason why he should not run, and consequently he did not follow our advice. On the day the marathon race took place the weather was extremely warm and our subject was one of the four who completed the race out of a field of seventeen. His time for the race, approximately 26 miles, was three hours and two minutes, which under the circumstances of the intense heat and of the altitude (approximately 6,000 feet above sea level) represented a performance of international standard. His condition after the race was surprisingly good and his recovery time was short as compared with that of the other competitors.

As this case appeared to us extraordinary, it was decided to investigate the subject further. Clinical investigations, supplemented by electrocardiographic and roentgenologic studies, were carried out over a period of four years. On several occasions, observations were made before and immediately after long distance runs. Our observations are here presented.

REPORT OF CASE

History.—G. M. is a carpenter. He states that during childhood he was very weak and that because of rickets he could walk only with the aid of metal supports. He suffered from the usual childhood diseases, such as measles, scarlet fever and whooping cough. At the age of 9 years he contracted a severe illness which, although he says it was thought to be typhoid, seems more likely to us to have been rheumatic fever, because at the time his joints were swollen and painful and the

physician believed that his heart was affected. It is also alleged that in the course of this illness he contracted pneumonia. In the following years he suffered from various complaints such as headache, biliousness, palpitations, vomiting and other minor ailments. He was, as he stated, a "cripple." At the age of 16 he was readmitted to the hospital, this time for treatment of "intestinal trouble," the nature of which he is unable to state. Shortly afterward, bilharziasis was diagnosed after he had passed blood in the urine for a considerable period. After approximately fifty injections of antimony and potassium tartrate the bilharziasis was cured. At the age of 19 he suddenly fell ill again with a high temperature and rigors. He did not regain full strength, but in spite of his poor condition, after persuasion by his friends, he decided to play rugby for his club on one occasion. After this game he collapsed and was taken in an unconscious state to a hospital. There his condition was regarded as so alarming as to warrant sending for his parents. He remembers neither the collapse nor the subsequent hospital treatment. According to his statements his joints, particularly the knees, were swollen, his temperature was 104 F. and his pulse was regular but slow. Only after having spent four months in bed could he walk again.

His legs were atrophied to such an extent that he could walk only with the aid of crutches. Shortly afterward he contracted malaria, with repeated attacks of rigor and fever, which were treated successfully with quinine and brandy. At the age of 25 he was the victim of a motor car smashup in which he received severe burns over the chest and, in addition, his right knee joint was pierced by a fragment of metal, later to be removed surgically. A short time afterward he underwent an operation for inguinal hernia, since which time he has remained in good health.

Athletic History.—Since 1932 he has undergone a hard and systematic athletic training. He has been remarkably successful as a long distance runner, having participated in fourteen marathon races, always completing the distance. He won the South African Marathon elimination race for the British Empire Games in 1934 in two hours and fifty-four minutes (distance approximately 26 miles). On two occasions he entered the annual 54 mile race from Durban to Pietermaritzburg and covered the distance in good time, his record for this race being eight hours twenty minutes. On numerous occasions he has run from Johannesburg to Pretoria, a distance of 36 miles. During the past two years his athletic performances have further improved; in September 1937 he competed successfully in two marathon races within eight days. At the time of writing (1939) his physical condition continues to be excellent and he is still racing regularly in competitive events as well as frequently running long distances at his own leisure. Recently he has commenced playing squash raquets and is now one of the most prominent players in Johannesburg.

Physical Examination.—The subject is tall and thin. His height is 5 feet 10 inches (178 cm.), his weight, 142 pounds (64.4 Kg.). His skin is somewhat pale but shows no exanthema or other abnormality. There is no edema. The lymph nodes are not enlarged. Examination of the central nervous system and of the respiratory, digestive and genitourinary systems reveal no abnormalities. The spleen and liver are not enlarged.

Cardiovascular System: The apical impulse is widespread, and its maximum is seen and felt in the fifth intercostal space 11 cm. from the midsternal line. It consists of a systolic thrust, followed by a slight second thrust, diastolic in time. A distinct thrill is palpable over the apical region, both systolic and diastolic in time. Two diastolic murmurs are heard. The one, early in diastole, is decrescendo, high pitched, soft and blowing in character. It is audible over the base and along the left sternal border, with the maximum intensity in the region of the third and fourth intercostal spaces, gradually disappearing in the direction of the apex. The other diastolic murmur, long, rumbling and low pitched, is heard only over a small area in the region of the apex and is accentuated when the patient leans toward the left side. These murmurs are considered as being indicative of the presence of aortic regurgitation and mitral stenosis respectively. The pulse rate is regular, with a frequency during rest (standing) of 70 per minute.

there being no pulse deficit. The pulse is collapsing in type and of large amplitude. The arterial walls are not thickened, irregular or tortuous. The blood pressure has varied on different occasions from 150 mm. of mercury systolic and 60 diastolic to 130 systolic and 45 diastolic.

Röntgenologic examinations of the heart were carried out on four occasions. In May 1936 the transverse diameter of the heart was 14.9 cm. and of the chest 30 cm., the ratio thus being normal. In December 1937 a careful radiologic examination carried out by Dr. Maurice Weinbren again revealed no enlargement of the cardiac silhouette in relation to the outline of the chest. There was no characteristic deformity of any portion of the heart, especially no left ventricular hypertrophy and no enlargement of the left auricle. With a barium sulfate swallow there was a rather marked aortic impression on the esophagus, but there was no increase of the pulmonary artery and the left auricular impression. There was no marked prominence in the region of the conus pulmonalis and also no definite prominence of the left auricle in the oblique view. The aortic arch was high and showed extremely marked pulsation. The lungs were of normal translucency, and no adventitious shadows could be seen.

ELECTROCARDIOGRAPHIC STUDIES

Electrocardiograms were obtained under different conditions. On one occasion immediately after a run of 20 miles serial electrocardiograms were taken at five minute intervals over a period of one and one half hours. The methods used for the analysis of the tracings were similar to those elaborated on in a previous paper.¹

Special consideration was given to time intervals and voltage changes which occurred in the various components, to the duration of the cardiac cycle, to the length of ventricular contraction and ventricular diastole, as well as to the sino-auricular-ventricular conduction time. The contour of the serial voltage changes in the various leads was studied and the observations were interpreted in the light of the recent studies published by Schlomka and his collaborators.² In this way it was found that the electrocardiographic reactions were such that it could be concluded that the myocardium and conducting mechanism were of a high standard of efficiency.

Vasomotor Collapse.—On three occasions one of us (E. J.) has had the opportunity of observing in our patient typical attacks of vasomotor collapse. On the first occasion the subject was running in a cross country race when, approximately a quarter of a mile before the finish, he appeared to be unable to maintain his balance and reeled from one side of the road to the other as if intoxicated. Within 220 yards of the finish he collapsed and fell to the ground, where he lay dazed and pale. After a few seconds he rose and, staggering toward the tape, completed the race, when he again collapsed. On this occasion he was deeply unconscious for one minute, dazed and incoordinate for a further fifteen minutes and remained weak and listless for the rest of the day. It is of interest that three days prior to the race he had had an attack of malaria with chills and fever.

Similar attacks occurred on two other occasions. One of these took place one afternoon while training before he had started running. Subsequent to this collapse he rested for a few minutes, after which he ran a distance of 4 miles. The style and speed of this performance, however, were noted to have been comparatively poor, although the patient himself was not aware of this fact.

COMMENT

The significance of this case lies in the relation it bears to the current views on the subject of the alleged dangers of exercise, and especially of what is termed "overexertion," to persons suffering from valvular dis-

ease of the heart. It is generally considered by medical men that patients with valvular disease of the heart should avoid exercise entailing undue exertion, such as competitive games, athletics, gymnastics and heavy manual labor, and that they should limit their activities to the milder forms of exertion, such as walking, golf and perhaps tennis. In fact, it is generally assumed that there exists a clear distinction between the effects on patients with valvular heart disease of light and of severe physical activities respectively. Moreover, in most instances the medical practitioner believes that such patients would actually be incapable of carrying out strenuous physical performances.

Although these views are applied chiefly when one is dealing with patients who are found to have diastolic murmurs, one encounters instances frequently in which physical activities are severely curtailed on medical advice because of the presence of uncomplicated systolic murmurs. With regard to the latter group of cases, such an attitude appears to be entirely unjustifiable in view of ample clinical evidence proving the benign nature of such murmurs, which in most instances do not even indicate organic valvular heart disease.³ One of us⁴ has described the case of the woman Olympic champion of the half mile race in 1928 who had previously been warned not to participate in athletic events because of the presence of an uncomplicated systolic murmur. Her disregard of this advice did not harm her in any way.

We have reason to believe that an attitude similar to that now held concerning uncomplicated systolic murmurs may also be tenable with regard to uncomplicated valvular disease of the heart presenting murmurs diastolic in time when these are due to aortic regurgitation and mitral stenosis or to aortic regurgitation alone, of rheumatic origin.

AORTIC REGURGITATION

There are several instances on record of persons with aortic regurgitation who showed noteworthy physical performances. One of us (E. J., 1936) presented the report of a man with aortic regurgitation of syphilitic origin who was able to carry out most strenuous industrial work, while the other (Suzman) has recently observed a man aged 34 years with aortic regurgitation of rheumatic origin who excels in long distance swimming. Parrisius⁵ reported on a German ski champion presenting the signs of aortic regurgitation. Robinson⁶ quotes Rudolph's report of a soldier aged 25 who, in spite of aortic incompetence as well as of "other valvular defects," was not only able to stand the stress of active service at the front for several years but actually out-rivalled his fellows as an athlete. Cotton's⁷ studies of soldiers indicate that aortic regurgitation is compatible with health, and he states that "disease of the aortic valve in itself gives rise to no symptoms." Robinson relates that he had an opportunity of seeing almost daily a colleague who had pronounced signs of aortic incompetence following rheumatic infection at the age of 5. Although he led an unusually active life and

engaged at one time in college sports, he had no symptoms. Finally, at the age of 32 he died of *Streptococcus viridans* infection. At autopsy the cusps of the aortic valve were extensively retracted and thickened and the left ventricle was hypertrophied but not greatly dilated.

Parade⁸ described three cases of aortic regurgitation: A man aged 20, although being aware that "there was something wrong with his heart," had never complained and had been a keen football player, cyclist, ski runner and paddler. Another patient of Parade's, aged 24, with aortic regurgitation who had rheumatic arthritis a few years previously, was a keen sportsman and successful in athletic competitions. The third patient was an athlete aged 20 with aortic regurgitation. This man, whose condition is stated to have been of a congenital nature, had during his school days freely participated in sports and exercises. Later he became a keen ski runner and participated in rowing regattas and in tennis tournaments.

Dietlen⁹ appears to be well acquainted with the fact that aortic regurgitation by no means makes outstanding physical performances impossible but considers it necessary to emphasize that great care must be exercised by persons in whom the condition has recently originated and that every person with aortic regurgitation must be kept under constant medical observation.

According to Warfield,¹⁰ during the examination of some 40,000 young recruits at a camp in 1918 there were a number of youths with aortic insufficiency who were athletes, some record holders, who were quite unaware that they had any heart lesions. While he holds that men with such heart lesions should not enter competitive sports, his observations indicate the extent to which the compensated heart, though mechanically embarrassed, is able to perform. Warfield concludes that the child with a heart lesion should not necessarily be made into a "softie," although he makes one exception in that he urges such an individual not to attempt to swim beyond his depth and not to participate in swimming races or to play water polo.

Matthes¹¹ described the case of a soldier who was actively engaged in military service for a period of twenty years following the occurrence of aortic regurgitation, an aftermath of scarlet fever.

In an attempt to give a pathophysiologic explanation of the fact that patients with aortic regurgitation often show a high degree of physical efficiency, Schneyer¹² made systematic investigations of the effects on rabbits of experimentally produced valvular defects. He observed that, while after mitral regurgitation, tricuspidal regurgitation, aortic stenosis and pulmonary stenosis the "medium blood pressure" returns to the preexperimental level, aortic regurgitation on the other hand leads to a considerable permanent drop of "medium blood pressure." The extent of the valvular destruction has no influence on this reaction. Systolic pressure in cases of aortic regurgitation was found to be mostly above the pretraumatic level. (Although Schneyer does not clearly define his term "medium blood pressure," we assume that he refers to a level

closely related to the diastolic pressure.) Fall of blood pressure leads to a lessening of the tone of the pressoreceptive nerves. Thus the precapillary bed constricts and prevents a further fall in blood pressure. Actually Schneyer has shown that the drop of blood pressure which immediately follows experimental production of aortic regurgitation in rabbits is doubled if the compensatory interference of the carotid sinuses is prevented by surgical denervation of these structures. Schneyer emphasizes that aortic regurgitation is the only valvular lesion in which nervous control from the carotid sinuses counteracts and compensates the hydrostatic effects.

MITRAL DISEASE

Jokl and Parade⁴ investigated the case of a cycling champion whose racing performances rapidly declined following an attack of rheumatic fever which resulted in stenosis of the mitral valve. It was pathetic to see how the patient tried in vain to overcome the handicap of his disease and how his courageous efforts to regain his former athletic prowess actually resulted in an acute severe breakdown during the race.

Among Dennig and Prodger's¹³ experimental subjects were two who suffered from mitral stenosis and regurgitation of rheumatic origin. No signs of decompensation were present. They stress that while healthy subjects show a parallel rise of circulatory minute volume and oxygen consumption, the two patients were unable to increase their minute volume in accordance with their oxygen demands. Their peripheral utilization of oxygen during exercise was considerably greater than that of the healthy subjects. It is of interest that, in spite of these unfavorable results, one of the patients was able to carry out strenuous work in a quarry, that he played football and that during his stay at the clinic the investigators were able to study his reactions to a long distance race. Prodger and Korth¹⁴ mention a patient with mitral stenosis and insufficiency who was compelled to discontinue exercise because hemoptysis developed. Using Knipping's apparatus, Marzahn¹⁵ examined a patient with mitral stenosis and regurgitation whose pulse rate rose to 222 a minute during exercise of medium intensity. His circulatory minute volume was low (6 liters) and his maximal oxygen intake was limited (1,200 cc.). A normal person whose circulatory reactions were studied as control showed during a performance test of considerably greater intensity a maximal pulse rate of only 150 a minute and an oxygen intake of 2,800 cc. a minute. Herxheimer¹⁶ writes that mitral stenosis always leads to an impairment of physical efficiency even if the deterioration of blood circulation is preceded by a short period of comparatively high working capacity of the heart. Edens¹⁷ draws attention to the fact that a hypertrophied and dilated right heart is sometimes responsible for a satisfactory functional capacity of the blood circulation during rest but that the emptying of blood depots during physical exertion often leads to a breakdown of the working ability of the left ventricle, the result being pulmonary edema. He illustrates his statement with a history concerning a young woman with mitral stenosis in whom pulmonary edema developed after a physical

performance of some magnitude. Edens concludes by saying that the heart is practically unable to compensate for stenosis of the mitral valve by myocardial adjustment such as occurs with other valvular defects. He therefore recommends the utmost care in the treatment of the condition and avoidance of strain of any description. The investigations made by Stewart and his collaborators¹⁸ show clearly that the functional capacity of the heart is always markedly impaired if stenosis of the mitral valve is present, while insufficiency of the aortic valve either as an isolated defect or as a superimposed defect on mitral stenosis is compatible with little or even practically no functional impairment.

Since stenosis of the mitral valve invariably causes a distinct impairment of physical capability, we believe that it is the hemodynamic disturbance peculiar to this valvular lesion, namely the defective filling of the left ventricle and the consequent venous congestion, which is the primary responsible factor, although it is understood that a poor myocardium must enhance the disability still further.

AORTIC REGURGITATION AND MITRAL STENOSIS

When mitral stenosis is accompanied by aortic regurgitation, the effects on physical efficiency appear to be entirely different from those which are observed with mitral stenosis alone.

Prodger and Korth¹⁴ carried out a study of the effects of light muscular training on six patients with valvular heart disease, three of whom had mitral stenosis and regurgitation with aortic insufficiency, while the other three had only mitral stenosis and insufficiency. The most striking improvement of physical efficiency during training was observed in the patients with the double valvular lesion, whereas the patients who failed to show favorable effects of training had disease of the mitral valve alone. "It might be thought," Prodger and Korth conclude, "that the changes which occur during training, whatever they are, are dependent on an adjustment between the greater and lesser circulations which can take place in the patient with a balanced disturbance, as it were, in both valves, whereas it cannot take place in a patient with the imbalance resulting from disease only of the mitral valve."

Nielsen¹⁹ states that aortic regurgitation and mitral stenosis together have a better prognosis than either alone. He adds that, of the two, aortic regurgitation is the more serious condition as far as life is concerned, while as far as work is concerned mitral stenosis is the more serious.

Stewart and his collaborators¹⁸ studied the effects of valvular heart disease on the dynamics of the circulation by observing the arteriovenous oxygen difference, cardiac index, cardiac output per beat, stroke volume per kilogram and left ventricular work per beat kilogram. As previously mentioned, they found that impairment of the functional capacity of the heart was less in those patients who suffered from a combination of mitral stenosis and aortic insufficiency, as compared with those who suffered from only mitral disease, and inferred therefore that aortic regurgitation is of functional benefit when superimposed on the mitral lesion. Aortic stenosis either alone or superimposed on the aforementioned valvular defects had an unfavorable effect.

It thus appears that the observations of other writers bear out the observations made on our patient, who in spite of the existing mitral stenosis, with its recognized unfavorable influence on working capacity, has been capable of extraordinary physical performances. It is reasonable to believe that, had the patient not had aortic regurgitation in addition, he almost certainly would have been unable to carry out the performances reported.

It is beyond doubt that his heart muscle is of the highest functional capacity. This is confirmed not only by the fact that the heart shadow is of normal size but also by the results of the electrocardiographic studies under conditions of severe muscular exertion. In view of our patient's high physical efficiency, this is what one would expect.

In view of the known benign effects of uncomplicated aortic regurgitation on physical performances, it is considered that the latter lesion (aortic regurgitation) has compensated for the disability expected from the coexisting mitral stenosis. In fact, we consider that overcompensation in this direction may have taken place, for, like Stewart and his collaborators, we have reason to believe that the presence of aortic regurgitation aids circulatory efficiency.

High pulse pressure, always regarded as a characteristic clinical sign of aortic regurgitation, has also been found in first class athletes²⁰ as well as in subjects with good resistance power against hot environment (Jokl and Weiner²¹), while an increase of pulse pressure has been observed during a period of systematic physical training in young recruits simultaneously with an improvement of endurance power.²² In other words, there is at least one hemodynamic factor which is common to subjects with a high standard of physical efficiency as well as to persons with aortic regurgitation. It must however be pointed out that high pulse pressure cannot be the only factor responsible for the high standard of physical efficiency, as it is well known that high pulse pressure is found in cases of hyperthyroidism and of beriberi, in which conditions physical efficiency is greatly impaired.

In addition to the case dealt with in this paper, we have recently studied two other athletes with mitral stenosis and aortic regurgitation, so that the fact seems to be established that the combined valvular lesion of mitral stenosis and aortic regurgitation and a high standard of physical efficiency are by no means irreconcilable.

SUMMARY

1. A marathon runner was observed to have mitral stenosis and aortic regurgitation.
2. The significance of this case is worthy of note in view of current opinions on the subject of the alleged dangers of exercise to persons suffering from valvular disease of the heart.
3. The recently adopted more liberal prognostic interpretation of systolic murmurs may also be tenable with regard to uncomplicated valvular heart disease presenting diastolic murmurs when these are due to combined aortic regurgitation and mitral stenosis or to aortic regurgitation alone, of rheumatic origin.

A STUDY OF "FALSE" FRIEDMAN
TESTS FOR PREGNANCY

LAWRENCE M. RANDALL, M.D.

THOMAS B. MAGATH, M.D.

AND

F. NORMAN PANSCH, M.D.

Fellow in Obstetrics and Gynecology, the Mayo Foundation

ROCHESTER, MINN.

In 1927 Aschheim and Zondek¹ reported that the urine of pregnant women contained large amounts of a substance capable of stimulating the ovaries in a manner similar to the action of the gonadotropic principle of the anterior lobe of the pituitary gland. This substance is now known as the anterior pituitary-like hormone. In 1928 these investigators² published the results of experiments in which they injected into mice the urine of pregnant women. Friedman³ in the following year noted that the ovary of the rabbit likewise responded to injections of urine obtained from pregnant women. In 1931 Friedman and Lapham⁴ published their application of this fact as a method of diagnosis for pregnancy. A survey of the reports published subsequently emphasizes the high degree of accuracy of the results obtained with the hormonal tests for pregnancy. However, these tests in common with other biologic tests are subject to errors, some of which may be due to faulty technic or may be inherent in the limitations of the test.

This report is based on 645 Friedman tests performed at the Mayo Clinic. Subsequent histories and observations established the presence or absence of pregnancy at the time the test was performed. Three hundred and two tests gave positive results and 343 gave negative results. Ten positive reactions occurred in the absence of pregnancy, and seven negative reactions were obtained when pregnancy was present. Thus, in 2.63 per cent of the tests the result was at variance with the ultimate diagnosis. The great majority of patients tested were those concerning whom the diagnosis of the presence or absence of pregnancy could not be determined definitely by history and physical examination at the time the Friedman test was performed.

The technic of the test is as follows: From 8 to 15 cc. of urine is injected slowly into the marginal ear vein of the rabbit. After forty-eight hours the animal is examined. Positive results of the test are indicated, on gross examination, by the presence of corpora hemorrhagica or corpora lutea or both. If these conditions are not clearly evident, the test is considered as giving negative results. Marked congestion of the uterus and oviducts is often strikingly present when the test gives positive results.

Certain precautions are observed in the performance of the test. The first urine passed in the morning is used and is injected within an hour or is kept on ice

until it is used. If the urine is cloudy it is filtered. Rabbits younger than 2½ months are not used, but no objection has been found to the use of older rabbits if they have not recently copulated. To preclude copulation and pregnancy, the test animals are isolated in single cages for three weeks before they are used.

Since Friedman described the test there has been a tendency to modify it and still refer to it as the Friedman test. Thus, certain authors have concentrated the urine, others have injected urine into the rabbits several times over a period of several days, and others have used very large quantities of urine. Since the test is based not only on the fact that the rabbit does not spontaneously ovulate but also that the ovary of the rabbit is relatively insusceptible to the anterior pituitary-like hormone and that there are large quantities of such hormones in the urine of pregnant women, it is necessary that the dose of urine be restricted to amounts not greater than advocated by Friedman. If rabbits are injected with 8 to 15 cc. of the first urine passed in the morning and a positive result is obtained, the deduction that the patient is pregnant is justified. The total error in such deductions will not be more than 3 per cent, which, when compared with other biologic tests, is almost unbelievably accurate. Many more positive results will be obtained if larger quantities of urine are injected, but under these conditions one is not justified in deducing that the patient is pregnant, although this will be true in a large percentage of cases. In like manner, if positive results are obtained when small amounts of urine are injected, one may conclude that there is more hormone similar to that secreted from the anterior lobe of the pituitary gland than is present in normal pregnancy. One can eliminate so-called false positives due to such conditions as hydatidiform mole and chorio-epithelioma by injecting small amounts of urine into rabbits when these conditions are suspected.

It is our purpose in this paper to consider the relatively small group of reactions (seventeen of 645) that did not coincide with the diagnosis of the presence or absence of pregnancy. The Aschheim-Zondek and Friedman reactions are often considered as tests for pregnancy per se. However, it must be remembered that these are tests for the detection of the presence in the urine of a substance (like that secreted by the pituitary gland) capable of stimulating the ovaries of the test animal. This substance (or these substances) may be found in the presence of several physiologic and pathologic states other than pregnancy. Therefore it is natural to expect that such a fact would affect the accuracy of the test for pregnancy. Thus the terms "false positive test" and "false negative test" have been avoided in this paper because, in spite of the fact that they may be false with regard to the presence or absence of pregnancy, they may be true with regard to the presence or absence of demonstrable quantities of the principle or principles in the urine. In other words, the so-called error is not usually due to a failure in the test itself but is due to an associated physiologic or pathologic condition.

In evaluating the reliability of the Friedman test it is important to know some of the conditions which may give positive reactions in the absence of pregnancy. A review of the literature discloses the following conditions as being associated with positive reactions given by nonpregnant women: spontaneous or artificial menopause, menstrual disorders, ovarian cysts, carcinoma,

treatment with anterior pituitary preparations, pelvic inflammatory disease, myxedema, gallbladder disease, genital tuberculosis and errors in technic.

MENOPAUSE

The menopause is one of the conditions which may give rise to a positive reaction from the urine of non-pregnant women. The decrease in ovarian activity associated with the climacteric is usually accompanied by an increased activity of the anterior lobe of the pituitary gland with a resultant increase in secretion of gonadotropic principle in an attempt to stimulate the failing ovary. Drips and others⁵ found gonadotropic principle present in the urine in excessive amounts in 57 per cent of a series of women during the menopause. The severity of the hot flushes experienced by these women varied directly with the degree of excess gonadotropic principle found in their urine. Mazer⁶ investigated the hormone content of the blood of women during the menopause. He found an excess amount of pituitary principle in about 60 per cent. The excretion of this principle in the urine may well account for the positive Friedman tests occasionally reported during the climacteric. Feresten,⁷ Hannan,⁸ Heiberg,⁹ Mills,¹⁰ Mull and Underwood,¹¹ and Ziserman¹² have reported positive pregnancy hormone tests given by menopausal women who were not pregnant. The group of patients studied by us included two cases in which positive Friedman reactions were given by nonpregnant women at the menopause.

Illustrative Case.—A woman aged 48 had been having irregular menses and hot flushes for eight years prior to coming to the clinic. In the past year she had had two periods of menstrual flow, the last of which had occurred three months prior to the performance of the Friedman test, which was reported as giving positive results. The hot flushes had been of increased severity during the past year. Her reply to our questionnaire revealed that she had not been pregnant.

MENSTRUAL DISORDERS

The same state of compensatory increased excretion of gonadotropic principle in the urine may occur in cases of pituitary-ovarian imbalance among younger women. In addition to irregular and abnormal menses, the patients may give complaints such as soreness of the breasts, increased nervousness prior to the menses, dysmenorrhea, menstrual migraine and occasionally menstrual edema or acne. It is reasonable to assume that the degree of severity of these subjective symptoms is usually proportional to the degree of disturbance of the normal relationship between the amounts of estrogenic hormone and gonadotropic principle. The amenorrhea that sometimes occurs in this type of case may be interpreted as a symptom of pregnancy, and further confusion may occur if a positive Friedman reaction is obtained. Studies of the blood or urine for estrogen

are important to establish a definite diagnosis. The concentration of estrogen is usually low or zero in the urine of patients with primary ovarian failure but is high in pregnancy.¹³ Estimations of pregnandiol are of value in the differential diagnosis in such cases. Wilson and one of us¹⁴ found higher values for this excretion product of progesterone in the urine in early pregnancy than in urine of women with normal or abnormal menstrual function.

Mull and Underwood,¹¹ Reinhart¹⁵ and Ziserman¹² have reported positive pregnancy reactions associated with menstrual disorders of nonpregnant women; the exact nature of the disorder, however, was not definitely stated.

Illustrative Case.—A woman aged 24 gave a history of irregular menses with a profuse flow of eight to ten days' duration and a period of amenorrhea for six months on one occasion in the absence of pregnancy. She had been amenorrheic for thirteen weeks when seen by us, and although physical examination revealed a questionably enlarged uterus its size did not correspond with that of a uterus after thirteen weeks of gestation. The Friedman reaction was positive. Another test, four weeks later, likewise gave a positive result. At the time of the latter Friedman test menstrual spotting had occurred for four days, without any particular discomfort, and continued for six days thereafter. Physical examination seven weeks later, with no menses in the interim, revealed no signs of pregnancy.

LOW BASAL METABOLIC RATE WITHOUT MYXEDEMA

The condition of nonpregnant patients who have a lowered rate of basal metabolism without myxedema, associated with amenorrhea and a positive Friedman reaction, might be considered to be ovarian failure secondary to deficiency of function of the thyroid gland. Bamforth¹⁶ reported one case of amenorrhea in which the basal metabolic rate was —37 per cent and the reaction to the Friedman test was positive although the patient was not pregnant.

Illustrative Case.—A woman aged 30 had had a sudden severe attack of gallbladder colic and cholecystectomy was advised. She gave a history of irregular menses; she had had periods of amenorrhea of from three to five months' duration. On one occasion she had menstruated for seven weeks. Her last menstrual period had occurred seven weeks before the physical examination, which revealed a slightly enlarged uterus and a slightly softened cervix. The Friedman test gave a positive result. At the time of cholecystectomy no evidence of pregnancy was found. Later the basal metabolic rate was found to be —19 per cent. Following treatment with desiccated thyroid the basal metabolic rate was raised to —5 per cent. Following this the menses appeared every six to eight weeks and the patient was subjectively better.

OVARIAN CYSTS

Ovarian cysts have on occasions been associated with positive reactions in the absence of pregnancy.¹⁷ Woodhouse¹⁸ reported two cases in which positive reactions were associated with tuberculous conditions involving the ovary. The explanation of the reaction is hypothetical but it is likely to be due to an endocrine imbalance.

ance in which again an attempt is being made to stimulate a functionally failing ovary by an excess of anterior pituitary principle.

Illustrative Case.—A woman aged 27 complained of a marked lower abdominal cramping pain which had appeared at the time of an expected menstrual period. However, there had been no flow until seven days later, at which time she had awakened from sleep with vaginal bleeding sufficient in amount to saturate three pads, followed by a decrease in flow such that there had been a mere spotting of blood. Simultaneous with the hemorrhage there had appeared a sharp pain in the right lower quadrant of the abdomen which had confined her to bed. Physical examination revealed a soft, tender mass in the right side of the pelvis. On the third day after the onset of bleeding, microscopic examination of tissue obtained by dilation and curettage disclosed no placental or decidual material. Fifteen days later a Friedman test gave positive results. An exploratory laparotomy revealed a corpus luteum cyst of the right ovary but no evidence of pregnancy. No subsequent evidence of intra-uterine or extra-uterine pregnancy was observed.

MALIGNANCY

Malignant tumors have been mentioned by some authors as a cause of positive pregnancy hormone reactions. Grant and his associates,¹⁹ Büttner²⁰ and King²¹ reported cases of carcinoma associated with positive reactions of women who were not pregnant. Zondek²² first claimed that 15 per cent of a series of patients suffering from malignant diseases gave the characteristic pregnancy response. Later, however, he²³ reported that the urine of women suffering from carcinoma usually produced only maturation of the follicles and rarely produced corpora lutea or follicles that were hemorrhagic. Our series of cases includes one in which a positive reaction was found in association with a squamous cell carcinoma of the cervix and probably with an ovarian cyst in addition.

Illustrative Case.—A woman aged 34 came to the clinic complaining of metrorrhagia and a clear, watery, occasionally bloody, vaginal discharge that had been present for two months. Examination revealed a squamous cell carcinoma of the cervix, stage 4. There was a large, soft anterior mass which appeared to be uterus. The patient's last period of menstrual flow had occurred four weeks before the specimen of urine was collected for the Friedman test. The test gave a positive response.

Radium therapy was instituted but was discontinued after one month owing to the presence of increasing discomfort from the large pelvic abdominal mass. This was incised and drained through a small abdominal incision; 2,000 cc. of an odorless, straw-colored fluid escaped. Later it was thought that the large soft mass, which seemed to be uterus, might well have been an ovarian cyst.

TUBAL PREGNANCY—THREATENED ABORTION

Since the anterior pituitary-like hormone found in the urine of pregnant women is generally conceded to be the product of chorionic villi, the hormone reaction in cases of tubal pregnancy and threatened abortion depends on the presence or absence of viable chorionic tissue. From positive reactions one may conclude that either an intact or growing placenta exists or that the

fetus has recently died. An absolutely negative reaction justifies the contention that the fetus no longer lives. Kurzrok²⁴ reported that he had not seen a hemorrhage from a ruptured tube in the presence of a persistently negative test.

HYDATIDIFORM MOLE—CHORIONIC EPITHELIOMA

The hormone titer may be extremely high in the urine of women who have a hydatidiform mole. The amount of hormone depends somewhat on the size of the mole, the contact with the maternal circulation and the amount of degeneration present in the mole. A positive reaction may exist as long as six weeks following expulsion of the mole. An extremely high concentration of the hormone should arouse a suspicion of chorio-epithelioma, and a persistently positive test for more than six weeks following expulsion of a mole definitely favors the diagnosis of chorio-epithelioma. Our experience with these two conditions is consistent with the positive tests reported by others.

MISCELLANEOUS

The experiences of others in various conditions are pertinent to a study of the causes of unaccountable positive reactions. Bamforth¹⁶ and Mull and Underwood¹¹ reported positive reactions given by women receiving anterior pituitary or anterior pituitary-like preparations. It should be remembered that specimens of urine of women receiving treatment for sterility or menstrual disorders, especially when receiving such preparations, or roentgenologic stimulation to the pituitary, may exhibit a positive Friedman reaction in the absence of pregnancy. Various authors have reported pelvic inflammatory disease, tubo-ovarian abscess, menorrhagia of puberty, hypertensive cardiac disease and cholecystitis as being associated with positive pregnancy reactions. Kraus²⁵ reported that increased intracranial pressure, such as that caused by tumors of the pituitary gland and compensatory hypertrophy of the pituitary gland must be considered as causes of increased excretion of gonadotropic principle in the urine. Never to be forgotten are the errors in technic which may appear in any type of biologic test.

NEGATIVE FRIEDMAN REACTIONS GIVEN BY PREGNANT WOMEN

A review of the literature discloses the following circumstances that may be associated with a negative reaction in the ovaries of the rabbit in the presence of pregnancy: performance of the test too early in the pregnancy, performance of the test prior to a miscarriage of nonviable chorionic tissue, a diluted specimen of urine, insensitivity of rabbit's ovary, hormone secretion in amounts insufficient to cause stimulation of the ovaries, and delayed injection of the urine with consequent deterioration of the anterior pituitary-like principle. Ovarian cysts have been found in examination of patients whose urine gave a negative result to the Friedman test.

In three of our cases of pregnancy that gave a negative reaction, the Friedman test was repeated at a later date and in each instance the second test gave a positive response. This serves to emphasize the importance of a second test when negative results to the test are obtained in the face of other evidence suggestive of

pregnancy. One of the specimens of urine tested was somewhat old, having been submitted several hours after voiding. Another patient submitted the second specimen of urine passed in the morning, which would be expected to be more dilute in hormone concentration than the first specimen.

It is quite generally recognized that a negative Friedman reaction earlier than six weeks after the last period of menstrual flow cannot be relied on, since the concentration of hormone in the urine prior to this time frequently is not sufficient to indicate a positive reaction. In five of our seven cases in which the urine to be tested was obtained between the sixth and seventh week after the last period of menstrual flow the reaction was negative, although the patients were proved subsequently to have been pregnant. From the results in these five cases, it seems likely that at times the hormone concentration may not be great enough to give a positive reaction before the seventh week.

It is interesting to note that two patients had been treated for syphilis and that each had had manifestations in the central nervous system.

Illustrative Case.—A woman aged 35 had her last menstruation forty-nine days before presenting herself for examination. She had experienced some nausea and vomiting for the past two or three weeks. Physical examination revealed a rather soft, slightly enlarged uterus and also a tender cystic mass high in the right pelvis. A Friedman test gave a negative reaction. Ten days later right salpingectomy was done for removal of a hydrosalpinx, and an intra-uterine gestation was then definitely diagnosed. A second Friedman test four weeks thereafter gave a positive response. She was delivered of a full-term baby forty weeks from the time of her last period of menstrual flow.

CONCLUSIONS

1. The Friedman test is based primarily on the fact that if anterior pituitary-like hormones are present in the urine in certain amounts they will be demonstrable by typical reactions in the ovary of the rabbit. While the test is not a test of pregnancy from an academic point of view, to all practical purposes it is so if the correct technic is followed.

2. Therefore the Friedman test is based on quantitative considerations. Excretion of the gonadotropic principle of the anterior lobe of the hypophysis in the urine in excess amounts may be responsible for a positive Friedman reaction in the absence of pregnancy.

3. Among the several physiologic and pathologic states other than normal pregnancy which may give a positive reaction are hydatidiform mole, chorio-epithelioma, the menopause, menstrual disorders such as primary ovarian failure, treatment with preparations of the anterior lobe of the pituitary gland and errors in technic.

4. A negative reaction to the Friedman test prior to the seventh week after the last menstrual period may not be conclusive, although authentic positive reactions may be obtained much earlier, frequently within four weeks after impregnation. A test that gives negative results before the seventh week should be repeated later.

Air Ambulances.—Airplanes were first used as ambulances rather inadvertently during the World War when pilots or observers flying over the enemy lines were sometimes wounded and yet able to fly back to their own landing fields where medical attention was available. France and England in 1919 were apparently the first countries to assign certain airplanes to the transportation of the sick and wounded.—Armstrong, Harry G.: *Principles and Practice of Aviation Medicine*, Baltimore, Williams & Wilkins Company, 1939.

VISUALIZATION OF THE CHAMBERS OF THE HEART

THE PULMONARY CIRCULATION AND THE GREAT BLOOD VESSELS IN MAN: SUMMARY OF METHOD AND RESULTS

GEORGE P. ROBB, M.D.

AND

ISRAEL STEINBERG, M.D.

NEW YORK

In 1938 we first described our method of visualizing the chambers of the heart, the pulmonary circulation and the great blood vessels and later published a detailed account of the technic and a summary of the results obtained in the first 133 cases.¹ Before that time there had been no practical way of visualizing the interior of the heart and of the intrathoracic blood vessels. Although the roentgen ray had become almost indispensable to the accurate diagnosis of heart and lung diseases, it gave an incomplete picture of the anatomy of the cardiovascular system, because the four separate chambers of the heart and their component parts were represented on roentgenogram and fluoroscopic screen by one shadow, and the intrathoracic blood vessels were seen indistinctly if at all. Roentgenologic diagnosis, therefore, had to rely on such indirect evidences of disease as alteration in the size, shape and pulsation of the cardiac and vascular shadows and the distortion and displacement of the esophagus, the trachea and the bronchi.

In other regions of the body such as the gastrointestinal, the genito-urinary and the tracheobronchial systems, more complete visualization of structure has been obtained by the use of contrast roentgenography; but this principle has heretofore had limited success when applied to the heart and the blood vessels within the thorax. In 1931 Forssmann² tried unsuccessfully to outline the interior of the heart by the injection of iopax into the right atrium through a catheter which he had introduced into a vein in the arm and advanced to the heart. In the same year Egas Moniz, Lopo de Carvalho and Almeida Lima³ succeeded in visualizing the pulmonary arterial tree by cardiac catheterization and the use of a 120 per cent solution of sodium iodide. Several years later Nuvoli⁴ visualized the thoracic aorta of two patients by puncture of the left ventricle and the ascending aorta, respectively, and the injection of sodium iodide. Two years ago Castellanos, Pereiras and Argelio Garcia⁵ described their method of outlining the superior vena cava, the right cardiac chambers and the pulmonary arterial tree in infants and in chil-

Because of lack of space, this article is abbreviated in *THE JOURNAL*. The complete article appears in the authors' reprints.

dren less than 14 years of age by the intravenous injection of diodrast and iopax. These authors, however, could not visualize the right side of the heart and the pulmonary vessels of older persons, nor could they visualize the left chambers and the aorta except fortuitously in a few instances of congenital shunt from the right to the left side of the heart.

METHOD

Technic.—Our method of visualization consists of two fundamental parts: (1) opacification of the chambers of the heart and the blood vessels within the thorax by the intravenous injection of a radiopaque solution (70 per cent diodrast) and (2) roentgenography of these structures at the moment of their opacification.

The procedure is performed in two stages. In the first one the patient is seated with his arm resting on a table, and a specially designed 12 gage Lindemann needle with stopcock attached⁶ is inserted into the principal vein at the elbow. After the position of the needle within the lumen has been verified by the injection of physiologic solution of sodium chloride, the circulation time from the needle to the pulmonary capillaries and to the carotid sinus is determined by modifications of the ether⁷ and the cyanide⁸ method respectively.

In the second stage, the patient is seated before the cassette in the position giving the best view of the structures to be visualized (table 1). A special 50 cc. Luer-Lok syringe having a 12 gage tip⁶ and containing from 30 to 45 cc. of the 70 per cent solution of diodrast⁹ is attached to the needle-stopcock unit and approximately 15 cc. of blood is drawn into the syringe.

All is now ready for visualization. Under the injector's direction the patient exhales forcibly and then, at the command "Breathe in" he inspires deeply and quickly, and the injection is begun. The inspiratory position is held until the diodrast has had time to reach the pulmonary arterial tree and the first exposure has been made. The patient then exhales passively and breathes in again just before the time for opacification of the left side of the heart. The injection of the diodrast should be completed within two seconds. Roentgenograms are made at the predicted time of arrival of the opaque solution in the

TABLE 1.—Optimal Positions During Visualization

Structure to Be Visualized	Positions
Superior vena cava	Frontal and lateral
Cardiac chambers	Left and right anterior oblique
Cardiac walls and ventricular septum	Left oblique
Pulmonary and aortic valves	Right and left oblique
Pulmonary artery	Lateral and frontal
Right pulmonary artery	Right oblique and frontal
Left pulmonary artery	Left oblique
Smaller pulmonary vessels	Frontal
Pulmonary veins	Frontal, right and left oblique
Thoracic aorta and branches	Left and right oblique
Abdominal aorta and branches	Frontal

regions to be visualized, the predictions being based on the ether and the cyanide circulation times. For the normal person the intervals between the injection and the opacification of the various divisions of the cardiovascular system are surprisingly short (table 2). Except for overpenetration, the roentgenographic technic is that ordinarily used for the heart and the lungs.

THE CLINICAL MATERIAL

A total of 486 injections has been made on 233 patients, of whom fifty-seven were normal, seven had mediastinal disease, eighty had heart disease and eighty-nine had lung disease.

6. Made by Becton, Dickinson & Co.

7. Hitzig, W. M.: Measurement of Circulation Time from Antecubital Veins to Pulmonary Capillaries, *Proc. Soc. Exper. Biol. & Med.* 31: 935 (May) 1934.

8. Robb, G. P., and Weiss, Soma: Method for Measurement of Velocity of Pulmonary and Peripheral Venous Blood Flow in Man, *Am. Heart J.* 8: 650 (June) 1933.

9. Diodrast, concentrated solution (70 per cent), manufactured by the Winthrop Chemical Company, Inc.

RESULTS

Our observations regarding the normal cardiovascular system¹⁴ and the changes occurring in mediastinal,¹⁵ cardiac¹⁶ and pulmonary¹⁷ disease will now be presented briefly.

Mediastinal Disease.—The value of visualization in the diagnosis of mediastinal disease has been demonstrated by the results obtained in our series of seven patients. Five patients exhibited collateral circulation from the upper extremities and other signs and symptoms indicative of obstruction of the superior vena cava. Complete occlusion of this vessel, however, was excluded in every case by visualization, but a significant

TABLE 2.—Average Normal Intervals Between Beginning of Injection and Opacification

Structure	Interval in Seconds
Superior vena cava and right atrium.....	1.5
Right ventricle and pulmonary arterial circulation....	2-3
Pulmonary veins and left atrium.....	5-7
Left ventricle.....	7-9
Thoracic aorta.....	8-10
Abdominal aorta.....	10-12

degree of stenosis was found in three instances. In the first of these the constriction was caused by metastases to the mediastinum from a primary carcinoma of the right upper bronchus. The second patient (figs. 1 and 2) showed conspicuous narrowing of the right innominate vein and the superior vena cava caused by a mediastinal tumor, which on necropsy proved to be a fibrosarcoma. There was extensive collateral circulation through the usual pathways of the thorax and shoulder girdle and, of greater interest, by way of the internal mammary and the azygos veins. In the third case the stenosis of the vena cava was caused by mediastinal Hodgkin's disease, which also compressed the right subclavian and innominate veins and occluded the left innominate vein, producing collateral circulation by way of the hemiazygos system. The vena cava of the next patient, who had a substernal goiter, was not involved, but instead there was stenosis of the right innominate vein and complete occlusion of the left one. The last person exhibiting the superior vena caval syndrome had dilatation of the superior vena cava and of the innominate veins and no demonstrable point of obstruction. Necropsy, however, showed that the pulmonary veins and the left atrium were obstructed by metastases from a primary carcinoma of the right bronchus.

In another case a huge teratoma caused displacement of the superior vena cava and stenosis of the left innominate vein, producing collateral circulation by way of the cervical vessels. At operation the tumor was found to be firmly attached only at the site of stenosis, and here troublesome hemorrhage followed its removal. The last patient had a deformity of the superior vena cava, displacement of the pulmonary artery to the left and compression of its right branch by tuberculous lymph nodes in the paratracheal and the right hilar regions.

Heart Disease.—Characteristic changes were observed in heart disease. In congenital heart disease direct visualization of the abnormal communication has not yet been possible in interatrial septal defect, interventricular septal defect and patent ductus arteriosus. However, convincing evidence of its presence in the first and last disorders was provided by the recirculation of blood

Fig. 1 (O. C., aged 62).—Malignant mediastinal neoplasm. Conventional roentgenogram, frontal position. Note widening of mediastinum, irregularity of right supra-cardiac border, infiltration of right lung with fluid at base and metastatic nodule underlying third left rib anteriorly.

of the descending aorta, the aortic constriction, the aneurysm and the rich collateral circulation by way of the innominate, the subclavian and the lateral thoracic arteries were visualized.¹⁰

The following observations were made on the twenty patients with rheumatic heart disease, mitral insufficiency and mitral stenosis: 1. The right ventricle was enlarged, owing to dilatation and hypertrophy of the inflow tract, and elongation and widening of the outflow tract. 2. The pulmonary artery was dilated and alone produced the prominent pulmonary arc in the frontal view; the conus arteriosus formed no part of it. 3. The accentuated hilar and parenchymal shadows were caused by engorged pulmonary blood vessels, and the pulmonary veins, not the left atrium, produced the elevation and stenosis of the left bronchus. 4. The left atrium was enlarged predominantly toward the right; the main body never reached to the left cardiac border in the frontal view, although its auricle not infrequently was visible below the pulmonary arc.

Three different types of syphilitic cardiovascular disease have been studied in eighteen cases: aortitis, aneurysm of the aorta and aortic insufficiency with left ventricular enlargement and dilatation. In the five cases of aortic insufficiency without circulatory failure there was generalized aortic dilatation most marked in the ascending aorta, and marked dilatation and hypertrophy of the left ventricle. Aneurysm of the aorta was demonstrated in eight instances, in three of which it had previously been unrecognized. In one unusual case, two aneurysms were discovered: the first one a fusiform dilatation of the ascending aorta, and the second a saccular aneurysm of the descending aorta. In six cases presenting syphilis, hypertension and widening of the supracardiac shadow, dilatation of the aorta was excluded and the apparent dilatation shown to be due

to enlargement of the aortic arch from "uncoiling" in two instances, while aortic aneurysm was proved in the remainder. Rounded shadows at the left hilus had been diagnosed as aortic aneurysm and neoplasm respectively in two cases of syphilis, but instead they were found to be aneurysms of the pulmonary artery and its main branches (figs. 3, 4 and 5).

In our eleven cases of hypertensive heart disease without cardiac failure there were moderate enlargement of the left ventricular cavity and wall and varying degrees of tortuosity, "uncoiling" and dilatation of the aorta. In one case these changes in the aorta were sufficiently marked to warrant the roentgenographic diagnosis of aneurysm, although it was later established by visualization that the prominence of the ascending aorta was due primarily to "uncoiling," in small part to dynamic dilatation. The arteries arising from the arch were generally found to be dilated and tortuous, and in one instance "buckling" of the innominate artery was discovered.

There was little demonstrable cardiac change but a pronounced degree of aortic disease in the eight cases of arteriosclerotic cardiovascular disease in which there had been neither hypertension, circulatory failure nor coronary thrombosis; the arteriosclerotic aorta was characterized by calcification and thickening of the wall, widening of the aortic arch due to elongation and "uncoiling," and elevation of the arch. By visualizing the lumen it was possible to demonstrate the intimal location of the aortic calcification and thereby verify the fact that the shadow which we had previously attributed to the aortic wall actually represented it.

Fig. 2 (O. C.).—Malignant mediastinal neoplasm. Contrast roentgenogram, frontal position, three and one-half seconds after beginning of injection. Axillary, subclavian and innominate veins, superior vena cava, right atrium, right ventricle with conus arteriosus, pulmonary artery and main branches opaque. Collateral circulation around shoulder girdle, intercostal veins, right internal mammary and azygos vein also outlined. Note irregularity and displacement of innominate vein and reversed direction of blood flow through the azygos, internal mammary and intercostal veins, indicated by arrows. In these illustrations IV indicates innominate vein; A2P, azygos vein; SVC, superior vena cava; RA, right atrium; RV, right ventricle; PA, pulmonary artery; RPA, right pulmonary artery; LPA, left pulmonary artery.

There was generalized cardiac enlargement and a large aneurysm of the left ventricle in our one patient who had had myocardial infarction previously. Although the inside of the aneurysmal sac could not be visualized, probably because it was filled with clotted blood, the left ventricular cavity was dilated and the ventricular wall from the aneurysm to the apex was extremely thin.

There were two cases of chronic constrictive pericarditis. In the first case in which there was auricular fibrillation, the pericardium had been partially resected previously with temporary improve-

ment, but because peripheral circulatory failure had recurred constriction of the pulmonary artery or of the pulmonary conus was suspected. Visualization, however, showed no stenosis but instead dilatation of the right ventricle and the left atrium, so that further

surgery was obviated. In the second case cirrhosis of the liver or constrictive pericarditis was suspected. Tremendous enlargement of the innominate vein and the superior vena cava and pronounced slowing of the blood flow into the heart supported the latter diagnosis, which was subsequently confirmed at operation and necropsy. Tuberculous pericarditis with effusion was suspected in another case, but the diagnosis could not be confirmed because there was no evidence of cardiac tamponade or failure; the electrocardiogram was normal and the roentgenkymogram and the pericardial tap were inconclusive. The presence of an effusion was proved beyond reasonable doubt, however, by demonstration of the normal size of the cardiac chambers and the tremendous thickening of the surrounding cardiac shadow.

Lung Disease.—Cardiovascular changes were also found in pulmonary disease. In our thirty-nine cases of tuberculosis the changes in the pulmonary circulation consisted of three main types: (1) diminished vascularity resulting from the narrowing and obliteration of blood vessels in the exudative tuberculosis and by the fibrosis in the productive type, (2) gross displacement of the intrathoracic cardiovascular structures

cases presenting advanced bronchiectasis, and there was also a striking decrease in the blood supply to the diseased area. In both bullous (two cases) and generalized emphysema (seven cases) there was diminished vascularity to the involved regions. The main branches of the pulmonary artery at the hili and in the lower lobes were enlarged, forming the so-called moustache, while in the midzone and outer zones, the vessels became small and wirelike. In five instances of primary carcinoma of the bronchus there was a decrease in the size and number of the blood vessels to the affected lobes. This, we believe, was due either to obliteration of the vessels by the suppurative process or to narrowing of the lumen from compression by the primary tumor or from metastases to neighboring lymph glands.

COMMENT

Our method of visualizing the anatomy of the heart and the thoracic blood vessels is unique, differing from preceding attempts in the completeness with which the cardiovascular structures are revealed and in the specialized technics used to secure opacification and roentgenography. These technical procedures are largely the result of applying a practical knowledge

Fig. 3 (A. W., aged 57).—Aneurysm of pulmonary artery, syphilis, silicosis. Note generalized mottling due to silicosis particularly prominent at the bases, small bulla at right apex with fibrotic strands extending below first rib anteriorly, fracture of fifth rib posteriorly and prominent rounded mass at left hilus. Moderate increase in transverse diameter of heart and of aortic arch. (From the Tuberculosis Service of Bellevue Hospital.)

Fig. 4 (A. W.).—Aneurysm of pulmonary artery; syphilis; silicosis. Contrast roentgenogram at four and one-half seconds. Superior vena cava, right atrium, right ventricle, pulmonary artery, right pulmonary artery and left pulmonary artery and their branches opaque. Note aneurysm of pulmonary artery with enlargement of both branches, particularly the left, accounting for double bulge at hilus in conventional roentgenogram. Hilus subdivision increased in size and prominence, whereas vessels in outer and midzones are decreased, characteristic of pulmonary fibrosis.

Fig. 5 (A. W.).—Aneurysm of pulmonary artery and main branches; syphilis; silicosis. Contrast roentgenogram, left anterior oblique position at five seconds. Superior vena cava, right atrium and pulmonary artery with right and left branches filled. Note dilatation of pulmonary artery and right branch (seen on end) and enormous aneurysm of left branch filling aortic window.

by extensive pulmonary fibrosis ("fibrothorax"), and (3) displacement and stenosis of the pulmonary artery by tuberculous adenitis. The cardiovascular changes occurring in "fibrothorax" and the impossibility of recognizing them without visualization are demonstrated in figures 6, 7 and 8. In the conventional roentgenogram the heart and the great vessels could not be distinguished at all, but with visualization these structures and their gross anatomy were outlined. Following pneumothorax in thirteen cases and thoracoplasty in six others, changes in both the peripheral vascular tree and the larger arterial divisions occurred, consisting mainly of avascularity of the collapsed lobes and displacement and rotation of the pulmonary artery and its branches at the hilus.²⁰

Enlargement of the right ventricle and the pulmonary artery with its branches was observed in the three

of the anatomy and the physiology of the circulation to the field of contrast cardiac roentgenography.

We believe that our method of cardiovascular visualization is sound in principle and that it is now past the experimental stage. No serious effect has followed 486 injections in 233 cases, although mediastinal, heart or lung disease was present in the majority. The reaction to the injection is slight, and the organic iodide compound diodrast is promptly eliminated by the kidneys without change. The procedure does not require costly new apparatus and so can be performed in the average x-ray laboratory. The patients may be ambulatory, since after-care is unnecessary. Contrary to earlier opinion, we now believe that the procedure is more difficult to perform than most diagnostic tests. The technic is exacting, requiring dexterity, precision, speed, team work and strict adherence to detail. Proficiency in the procedure however, can be readily acquired through training and practice, and successful performance should be within the capability of every medical center.

20. Steinberg, Israel; Robb, G. P., and Roche, U. J.: A Visualization Study of the Circulatory Changes Resulting from the Collapse Therapy of Pulmonary tuberculosis, to be published.

Cineroentgenography of the heart and the thoracic blood vessels during opacification²⁵ has recently been carried out and shows graphically the cardiovascular anatomy, the changes occurring with the heart beat and the course and the velocity of the blood flow. Roentgenkymography during opacification²⁶ has been of value in identifying the structures causing external cardiovascular pulsations and in demonstrating intra-cardiac motion. By its use greater accuracy in measuring the cardiac output by roentgenkymography²⁷ should be possible because the true cardiac border can be defined and both ventricles visualized.

Detailed cardiovascular visualization has already proved its worth in clinical medicine and in the teaching of medicine and the anatomy, pathology and physiology of the circulation. A summary of its value in mediastinal, heart and lung diseases was given in the preceding section. By its use the mediastinal contents are divided in two main groups—the vascular and the nonvascular structures. Then the various components of the cardiovascular system are identified, and the location and the degree of gross abnormality ascertained. Nonvascular disorders such as neoplasm, cyst and tuber-

mass. This method of delineation is illustrated by figures 1 and 2.

In cardiovascular disease, this method has given a degree of precision in diagnosis previously unattainable. The single cardiac silhouette has been divided into its four constituent chambers, and blood vessels previously seen indistinctly have become visible. As a result, surmise regarding the chambers of the heart, the pulmonary circulation and the great vessels during life can be replaced largely by fact. The size, the shape and the location of each gross anatomic division can be determined and the site and the degree of abnormality ascertained. Instead of using arbitrary diameters in cardiac mensuration which frequently have no anatomic counterpart, one can now measure the actual length, depth and breadth of the heart and, more important, the dimensions of the chambers, the thickness of their walls and the diameter and length of the large blood vessels. Determination of the volume of the heart should consequently be more accurate. It is even conceivable that a practical index of the cardiac

Fig. 6 (J. D., aged 20).—Massive unilateral pulmonary fibrosis ("fibrothorax") due to tuberculosis. Conventional roentgenogram. Entire left side of chest obscured by extensive pulmonary tuberculosis. Note cavities below clavicle, displacement of trachea and other mediastinal structures, and impossibility of distinguishing heart. Right side of chest clear save for productive tuberculosis at right apex and first interspace. (From the Tuberculosis Service of Bellevue Hospital.)

Fig. 7 (J. D.).—Tuberulous "fibrothorax." Contrast roentgenogram three seconds after beginning of injection. Entire right side of heart visualized: left cephalic, axillary, subclavian and innominate (in part) veins, superior vena, right atrium, right ventricle, pulmonary artery, right pulmonary artery and branches are opaque. Left subclavian and innominate veins (indicated by white arrow) kinked and foreshortened, and superior vena cava displaced to left of spine. Entire heart rotated toward left axilla, giving view ordinarily seen in right anterior oblique position of thorax. Two pulmonic cusps and sinuses are indicated by outer black arrow. Note dwarfed receding left branch of pulmonary artery seen on end (upper black arrow) and avascularity of left lung, contrasting strikingly with normal right pulmonary artery and rich vascular network of right lung.

Fig. 8 (J. D.).—Tuberulous "fibrothorax." Contrast roentgenogram at eight seconds. Entire left side of heart visualized: left atrium (LA), left ventricle (LV), entire thoracic aorta (Ao), with its branches from arch, and abdominal aorta are opaque. Note two cusps and corresponding sinuses of aortic valve and innominate artery (AI) dividing into right common carotid and subclavian branches; on the left side left common carotid and more medial left vertebral arteries are indicated by vertical arrows and left subclavian and axillary arteries by horizontal arrow.

culous adenitis can be detected or better defined by the vascular derangement they produce. Most frequently there has been compression and displacement of the superior vena cava and the innominate veins, but the pulmonary blood vessels, the aorta and the heart have also been involved. By knowing the points of involvement of the cardiovascular system, which extends widely through the superior, the middle and the posterior parts of the mediastinum, one can map out the approximate size and configuration of the mediastinal

weight may ultimately be obtained by subtracting the combined volumes of the chambers from the total cardiac volume and multiply-

ing the result by the average specific gravity of the heart. Finally, the circulation time to each major subdivision of the intrathoracic cardiovascular system can be measured objectively, and with the same injection the peripheral arterial rate of blood flow²⁹ can be determined subjectively by the sensation of heat that spreads throughout the body.

The most striking results are obtained in disorders such as aneurysm of the pulmonary artery, aortic disease, pericardial and congenital abnormalities in which recognition is difficult or impossible with conventional methods of study. The importance of accurate diagnosis in such cases becomes apparent when one realizes

that excision of an aneurysm of the pulmonary artery wrongly diagnosed as neoplasm has been attempted,³⁰ once with fatal results.³¹ Likewise, the differentiation of neoplasm and aortic aneurysm is of vital importance in the presence of bronchostenosis and pulmonary suppuration, because excision or irradiation may be indicated in the first case and antisyphilitic treatment and wiring of the aneurysm³² in the second one. Another use may be the exclusion of other congenital lesions of patients with patent ductus arteriosus for whom ligation of this vessel is proposed.³³

In the lungs, visualization reveals intrinsic abnormality of the pulmonary blood vessels and also the changes caused by pulmonary disease. The greatest value of this method is in disorders near the hilus, which are notoriously difficult to diagnose. Enlarged lymph nodes, cysts and neoplasms can be differentiated from the hilar blood vessels and a clearer idea of their location and configuration gained from the vascular compression and displacement which they produce. Aneurysms of the pulmonary arterial tree can now be distinguished with certainty and differentiated from the nonvascular mass with transmitted pulsation which may simulate aneurysm. Rounded opacities not infrequently mistaken for calcified lymph nodes are shown to be arteries seen on end.

The diagnosis of parenchymal disease can usually be made by ordinary methods of study; but even in these obvious disorders we have found visualization worth while, for it brings out strikingly the pathologic changes in the pulmonary circulation and so presents a clearer picture of the primary disease. In cases of tuberculosis, fibrosis, emphysema, chronic pulmonary suppuration, cyst or neoplasm there is a decrease in the vascularity to the involved regions, while in other portions there appears to be an increase in the size and number of blood vessels (figs. 6, 7 and 8). This method has been of no value in the diagnosis of early tuberculosis or cavitation. It may, however, reveal the presence of hilar or mediastinal metastases too small to be detected otherwise in a case of primary carcinoma of the bronchus and so prove the case inoperable. In many instances of so-called peribronchial fibrosis the lung markings were shown to be due to normal pulmonary blood vessels instead of disease, and the increased lung markings in mitral stenosis and left ventricular failure which may be mistaken for tuberculosis or fibrosis are primarily due to dilatation of the pulmonary blood vessels.

In undergraduate and postgraduate teaching, the chief value of the method lies in its application to the basic sciences of anatomy, pathology and physiology and to the clinical subjects of roentgenology and medicine. In the past, the gross anatomy and pathology of the cardiovascular system have been taught chiefly by anatomic dissection and postmortem roentgenographic studies in which there has necessarily been great distortion. For this reason it has been difficult for the student to form a true picture of the heart and the blood vessels during life and to understand their relationships to one another and to adjacent organs. The use of contrast roentgenograms showing the loca-

tion, size and shape of the superior vena cava and its tributaries, the chambers of the heart, the walls and the valves, the pulmonary blood vessels and the aorta with its branches in health and in disease would simplify and enrich the teaching of these subjects. Contrast roentgenography likewise opens a new field for the study of cardiovascular physiology which heretofore has been based chiefly on animal experimentation supplemented by such indirect studies in man as electrocardiography, roentgenography and measurement of venous and arterial blood pressures and of the rate of blood flow. Now, however, both internal and external cardiac motion and the vascular pulsations occurring in the cardiac cycle can be studied in both animal and man.

The knowledge gained by this method will be useful for the instruction of the general practitioner as well as the specialist in roentgenology, heart disease and diseases of the chest. To the busy practitioner with limited time for postgraduate study, this method not only simplifies roentgenographic interpretation but also shows him gross pathologic changes in the living and so enables him to obtain a grasp of the fields of cardiac and pulmonary diseases which were previously beyond his reach. Since the use of fluoroscopy is becoming general, a knowledge of the structures responsible for the cardiovascular and pulmonary shadows in health and disease is necessary if errors are to be avoided and the maximal value of this diagnostic procedure secured. To the specialist, visualization offers a unique method of learning the anatomy and the pathologic conditions of the cardiovascular system by the study of roentgenograms showing normal structure and the changes in disease, supplemented by visualization studies of his own patients presenting diagnostic problems. Although roentgenology has long been known as "pathology in the living," it has heretofore given an inadequate insight into the condition of the heart and of the thoracic blood vessels. Now this term is more truly applicable in thoracic disease because contrast roentgenography reveals the gross anatomy of the heart and of the thoracic blood vessels, which previously could be learned only at necropsy.

SUMMARY AND CONCLUSIONS

Our method of visualizing the chambers of the heart, the pulmonary circulation and the great blood vessels in man consists of two parts: (1) the rapid intravenous injection of enough radiopaque solution (diodrast 70 per cent) to make the interior of the heart and of the thoracic blood vessels opaque to the roentgen ray, and (2) roentgenography of these structures at the time of their opacification. Specialized technics are necessary in both opacification and roentgenography.

The method is safe and practical. No serious consequence has followed 486 injections of 233 patients, many of whom were seriously ill. The usual reaction to the injection is mild and transient, and severe reactions are rare. The compound diodrast has negligible toxicity and is excreted rapidly and completely by the kidneys. This procedure does not require expensive new apparatus and can be performed in the average roentgenographic laboratory. Success demands a high degree of teamwork and precision and rigid adherence to the technic in all details.

The following conclusions seem warranted:

1. Our method of visualizing the chambers of the heart, the pulmonary circulation and the great blood vessels in man is safe and practical.

THE SYNERGISM OF PHENOBARBITAL, DILANTIN SODIUM AND OTHER DRUGS

IN THE TREATMENT OF INSTITUTIONAL EPILEPSY

BENJAMIN COHEN, M.D.

NATHANIEL SHOWSTACK, M.D.

AND

ABRAHAM MYERSON, M.D.

BOSTON

Pharmacologically the history of the treatment of epilepsy may be divided into several epochs. The first, which was inaugurated in 1853, lasted until the introduction of phenobarbital and may be called the era of the bromide treatment. Bromides undoubtedly reduced the epileptic attacks but on the whole did not represent a very efficient form of therapy, and their effective use was hindered by the frequent occurrence of bromidism.

The second era came with the introduction of phenobarbital in 1912. The profession recognized that this drug was more successful than bromides in the treatment of epilepsy, and in a short time bromides receded to a position of secondary importance.

The third era is very recent in origin and is characterized by the introduction in 1938 of dilantin sodium by Merritt and Putnam,¹ whose work established the specific value of this drug.

It is certain that there is no unified condition which can be called epilepsy. It has long been known that the convulsive syndrome not only comes without known cause (the so-called idiopathic epilepsy) but is often a concomitant of infectious diseases, kidney damage and organic disease of the brain due to such conditions as syphilis, arteriosclerosis and brain tumor. In other words, there are various avenues of causation. On a theoretical basis, therefore, there should be different avenues of therapeutic approach, and even where the etiology is unknown it seemed to us that a synergistic approach to the pharmacologic treatment of epilepsy would be of value.

EXPERIENCE WITH PHENOBARBITAL

Phenobarbital Alone.—At the beginning of this research, over two years ago, the patients who were institutionalized at the Grafton State Hospital were treated almost entirely with phenobarbital in what we now recognize to have been inadequate dosage. By what we call "central control," namely the handling of all patients by a few physicians rather than by the individual physicians in charge of their respective services.

Read at the twenty-ninth annual meeting of the American Psychopathological Association, Atlantic City, N. J., June 5, 1939.

Parke, Davis & Co. furnished the dilantin sodium used in these experiments; Smith, Kline & French Laboratories supplied the amphetamine sulfate.

From the Grafton State Hospital, North Grafton, Mass., and the Division of Psychiatric Research, Boston State Hospital, aided by grants from the Commonwealth of Massachusetts and the Rockefeller Foundation.

1. Merritt, H. H., and Putnam, T. T.: Sodium Diphenyl Hydantoinate in the Treatment of Convulsive Disorders, *J. A. M. A.* 111:1063 (Sept. 17) 1938.

the dosage of phenobarbital was raised in each case in accordance with the number and the time of occurrence of the epileptic attacks.

Such increases in dosage were made until it was evident in each case that phenobarbital had reached the limit of usefulness and that further increase could not reduce seizure incidence. By this use of phenobarbital alone we were able to effect improvement in 89 per cent of all patients treated, with a total seizure reduction of 68 per cent.

The average daily dose of phenobarbital used was 2.9 grains (0.188 Gm.) per patient, ranging from 1.0 to 8.0 grains (0.06 to 0.52 Gm.) a day. Detailed results of this treatment have been published elsewhere.² We recapitulate some of the observations in order to compare them with the effects of the synergistic treatment to be described later.

We had observed that epileptic patients show individual rhythms with fair constancy: annual seizure rates (under unchanged medications) tended to approximate one another, and loads of seizures seemed to favor set periods of the day. Accordingly after data were reviewed each week or two the dose of phenobarbital immediately prior to the individual seizure peak was increased by from one half to 1 grain (0.03 to 0.06 Gm.) until it was evident that further increase was without benefit. In this way we achieved what we conceived to be the most favorable therapeutic levels with phenobarbital.

The following remarks may be made about the use of phenobarbital in epilepsy: Phenobarbital appears to exercise diffuse antiepileptic effect with benefits manifested in every hour period of the day even though it is given only a few times daily. This is probably due to accumulation of the drug in the body and its gradual excretion, the reservoir level being maintained by continued medication.

It appears from our studies that there is an optimal dosage of phenobarbital beyond which no benefit is obtained by increasing the dosage. When administered to patients who are inadequately treated, it exerts a rapid and sustained beneficial effect. As the level of dosage is raised arbitrarily, most of these patients tolerate the drug without untoward effect but additional antiepileptic benefit is not observed.

This point is demonstrated in table 1 by the record of twenty patients whose expectancy of seizures on the basis of the previous two years was 427 in ten weeks.

We find no support for the opinion so far expressed to the effect that the dose of phenobarbital must be regularly increased in order to obtain therapeutic benefits. Our observations, as presented in table 2, involve thirty unselected cases over four periods of ten weeks each, during which the dosage of the drug remained unchanged.

Toxicology of Phenobarbital and the Use of Amphetamine (Benzedrine) Sulfate.—We wish to present certain facts on the toxicology of phenobarbital and the value of amphetamine sulfate in its treatment. Toxic symptoms were surprisingly low in this group of patients. Of the 144 patients under treatment in this series, seventy-two received daily totals of 3 grains (0.2 Gm.) or more of phenobarbital daily. Of this series one case presented symmetrical dermatitis of the hands which disappeared within two weeks when the drug was discontinued and reappeared when medication was

2. Cohen, Benjamin, and Myerson, Abraham: The Effective Use of Phenobarbital and Benzedrine Sulfate (Amphetamine Sulfate) in the Treatment of Epilepsy, *Am. J. Psychiat.* 95:371-393 (Sept.) 1938.

resumed. There were nineteen cases of drowsiness, in some instances with associated unsteadiness or functional ataxia. This unsteadiness was associated with drowsiness and a feeling of dizziness and does not represent true ataxia. So far as we know, there are no ways of predicting which patients will show drowsiness or unsteadiness. Despite the fact that phenobarbital is excreted by the kidneys and impaired kidney function might be expected to produce phenobarbital poisoning,³ we found no such correlation in our series.

That the toxic symptoms are due to some idiosyncrasy is indicated by table 3, which shows that they occur without definite relationship to the dosage.

In our previous paper we pointed out that amphetamine sulfate is valuable in counteracting the drowsiness and unsteadiness of phenobarbital. One of the main characteristics of this drug is its effect on drowsiness and sleep. It effectively dissipates the drowsiness and sleepiness of phenobarbital without in any way affecting the epileptic attacks, although in one instance it seems to have exerted a favorable influence. In general it may be stated that it neither increases nor decreases the epileptic attacks by itself.

On the basis of this action of amphetamine sulfate, we administered it in doses of from 5 to 25 mg. daily to patients who showed drowsiness with or without unsteadiness. Although phenobarbital dosage remained unchanged, the drug cleared up these symptoms in most cases within a day.

In order to determine the safety of such supplementary medication, we continued administration of amphetamine sulfate for an average period of seventeen weeks. The results, so far as attacks were concerned, were practically unchanged, although the group as a whole improved markedly with regard to drowsiness and general alertness. One patient, who had been receiving 5 grains (0.32 Gm.) of phenobarbital a day without benefit, improved markedly after amphetamine medication was started (table 4).

During the past forty-two weeks this patient has not been receiving amphetamine, and her seizure incidence in this period has been 0.1 seizure per week.

TABLE 1.—Effects of Mounting Phenobarbital Dosage

Time, Ten Week Period	Average Daily Dose of Phenobarbital, Grains	Total Seizures in Ten Weeks
1st.....	2.3	118
2d.....	3.2	108
3d.....	3.6	97
4th.....	3.7	100
5th.....	3.8	102

TABLE 2.—Effect of Unchanged Phenobarbital Dosage

Time, Ten Week Period	Total Seizures
1st.....	91
2d.....	67
3d.....	79
4th.....	73

Most of our patients lost weight, the loss ranging between 3 and 19 pounds (1.3 and 8.6 Kg.), the average being 6½ pounds (2.9 Kg.). The weight loss occurred during the period of amphetamine medication, which averaged seventeen weeks.

To summarize, amphetamine sulfate is of real value in the treatment of the drowsiness and unsteadiness

consequent on phenobarbital medication. The dosage of phenobarbital may be maintained during the period of amphetamine medication, and thus the penalty of increased attacks attendant on discontinuing phenobarbital or lessening its dosage is avoided. Another point which bears on the hypothesis raised by Merritt

and Putnam is pertinent at this time. It is apparently not the hypnotic effect of phenobarbital which is of value in the treatment of epilepsy, since this hypnotic effect may be eliminated by the use of amphetamine, and yet the seizure incidence is favorably affected.

DILANTIN SODIUM

In 1938 Merritt and Putnam described the value of dilantin sodium, a derivative of glycolyl urea, in the treatment of epilepsy in patients who derived little or no benefit from the usually accepted treatments (with bromides, phenobarbital, ketogenic diet, restricted fluid intake and other means). Using doses ranging from 0.3 to 0.6 Gm. a day for 142 patients, they found that the attacks were completely relieved in 58 per cent and greatly decreased in frequency in an additional 27 per cent.

Our studies of the effect of this drug may be divided into two parts, with (1) dilantin sodium replacing phenobarbital and (2) dilantin sodium and phenobarbital in combination.

Dilantin Sodium Replacing Phenobarbital.—Eighteen patients who were receiving optimal doses of phenobarbital were given supplementary dilantin sodium for five weeks. The amount of phenobarbital received was unchanged during this time.

It will be observed in table 5 that during the preceding five weeks (when they received phenobarbital alone) the total number of seizures was forty-one; while in the five weeks in which they received supplementary dilantin sodium they had nineteen seizures, a reduction of 54 per cent. Five patients were improved under supplementary dilantin sodium medication (total decrease of twenty-eight seizures mainly due to benefit in two of these patients); four patients had more seizures (total increase of only six seizures), and nine

3. Weiss, Soma: The Clinical Use and Dangers of Hypnotics, J. A. M. A. 107: 2104 (Dec. 26) 1936.

patients, who were free from seizures with phenobarbital alone, remained seizure free after dilantin sodium had been added.

In the succeeding three weeks phenobarbital for this group was gradually discontinued entirely; then

followed twenty weeks when dilantin sodium was administered, the maximal dose being six capsules (each containing 0.1 Gm. of the drug) daily for each patient.

It will be noticed in table 6 (which compares seizure totals in this twenty week period with those in the preceding period of twenty weeks with phenobarbital alone) that dilantin sodium is an inadequate substitute for adequate phenobarbital. In the twenty weeks in which these patients received dilantin sodium alone they had a total increase of 203 seizures as compared with the number of seizures when they received pheno-

barbital alone: Four patients who had been seizure free while given phenobarbital had a total of fifteen seizures in the twenty week period while they were receiving dilantin sodium alone. Fourteen patients (including the four already mentioned) had more seizures with dilantin sodium (total increase of 203 seizures in twenty weeks with dilantin sodium alone). One patient had one seizure in each of these periods. Three had fewer

seizures (total decrease of five seizures) with dilantin sodium alone than with phenobarbital alone.

The next step was return of these patients to phenobarbital medication. All these patients continued to receive six capsules (0.1 Gm. each) of dilantin sodium daily. When two successive periods of seven weeks each were subsequently compared it was found that resumption of phenobarbital medication effected improvement in ten cases with a total decrease of 239 seizures; five patients who had been seizure free with dilantin sodium remained seizure free, and two patients were unaffected. None showed untoward results. The total reduction of seizures effected by the addition of phenobarbital to existing dilantin sodium therapy was 89 per cent. The greatest change was noted in patient A. L., whose seizures dropped from 166 to seven. With his data excluded from the totals it is found that the remainder of the group experienced 79 per cent reduction of seizures. Details are recorded in table 7.

Dilantin Sodium and Phenobarbital (Twenty-Three Patients).—This phase of our study with a separate group of patients confirms the existence of synergism between phenobarbital and dilantin sodium.

The patients in this series were receiving heavy doses of phenobarbital and it was evident that additional increases of this drug would be without benefit. Consequently the phenobarbital dosage was retained without change and supplementary dilantin sodium was used.

The average period during which supplementary dilantin sodium was used was twenty-five weeks. The average dose of phenobarbital per patient was 4 grains (0.26 Gm.). The average maximum dose of dilantin sodium was 0.3 Gm. (4½ grains) daily. The total number of seizures during the period of phenobarbital plus dilantin sodium was 330 by direct count and the total number of seizures in an exactly equal period while patients were receiving phenobarbital without dilantin sodium was 662. The reduction of seizures by the added dilantin sodium amounted to 50 per cent and twenty-two of the twenty-three patients in this series showed improvement. These data are in agreement with those observed in the first part of this study, when the administration of dilantin sodium in addition to the existing phenobarbital medication over a period of five weeks reduced the total seizure incidence 50 per cent.

It will also be noted that our clinical results with a combination of phenobarbital and dilantin sodium were far superior to those observed when dilantin sodium was used alone (although the maximum dose of dilantin sodium in the latter instance was 0.6 Gm. a day in contrast to an average maximal dose of 0.3 Gm. in the former instance). Individual and group data are listed in detail in table 8.

Toxicology of Dilantin Sodium.—Most of the toxic features observed occurred in the group of patients for whom replacement of phenobarbital by a maximum dose of 0.6 Gm. of dilantin sodium daily was attempted.

One patient refused further dilantin sodium after a short trial, saying "It dazed me, upset my stomach as though I had indigestion and made me dozey all the time." (He was dropped from the study.) Five of the forty-one patients who received dilantin sodium became drowsy and unsteady after dilantin sodium dosage had reached its peak, and bed care became necessary. Medication consisted of administering from 30 to 40 mg. of amphetamine sulfate in divided doses over a period of two days. In most cases drowsiness was relieved the first day and difficulty of gait by the second day. The dilantin sodium dosage remained unchanged throughout this period.

LAXATIVE DRUGS

In a previous paper we mentioned the omission in a series of cases of the old routine administration of magnesium sulfate by mouth twice weekly in the treat-

* On account of a cutaneous idiosyncrasy this patient was receiving bromides instead of phenobarbital.

ment of epilepsy. For this group we also discontinued intestinal lubricants, enemas and all other laxatives. This program has been in effect about a year, and throughout that time these patients have continued to receive adequate phenobarbital. We now confirm our original impressions and wish to point out that the elimination of routine laxatives has been followed by neither gastrointestinal difficulties nor increase of seizures.

COMPARATIVE AND GENERAL EFFECTS OF THE DRUGS USED

In table 9 we compare the percentage reductions of seizures produced by the various drugs.⁴

By comparing total hospital seizure incidence in the past one and one-half years with the number of attacks expected on the basis of record, we estimate that we

have spared our patients over 8,000 seizures by our various therapeutic programs (a reduction of 71 per cent). This great reduction has been paralleled by an improvement in the whole atmosphere of the wards in which these patients are confined. Accident incidence, previously high, has been lowered to the point of infrequency. The patients have become easier to handle, and in consequence privileges have been increased. Many of them have been able to achieve residence in more desirable wards and also work assignments, previously denied them, because of risk. Status epilepticus, previously common, is now a rarity. Residual seizures are far less severe, and the present trend is so promising that we expect more favorable results in the future.

SUMMARY

Patients with severe epilepsy confined in the Grafton State Hospital have been given intensive and extensive pharmacologic treatment. The increase of phenobarbital dosage up to an average of about 3 grains a day per patient, with due regard for the individual effect, has been attended by great reduction in seizure incidence, amounting to about 68 per cent when compared with treatment by phenobarbital alone given in a routine way and haphazardly.

Dilantin sodium alone has not exerted as favorable an effect in reducing seizure incidence as adequate phenobarbital dosage.

The use of amphetamine sulfate is recommended because of its value in dissipating the untoward effect of idiosyncrasy or excessive doses of phenobarbital. It also has a favorable, although somewhat less marked, effect on the toxic manifestations of dilantin sodium. Furthermore, it permits these drugs, especially phenobarbital, to be continued in unchanged dosage, even though this dosage by itself produces untoward results and when the reduction of dosage would result in increased attacks.

More striking and most important is the synergism existing between phenobarbital and dilantin sodium. The combination is far more efficient than either drug used alone, the reduction in seizure incidence being at least 50 per cent over the most favorable results

4. Figures were determined by the ratio of the weekly seizure incidence under a given drug or drug combination with the number of seizures expected weekly on the basis of individual records in the two years prior to the start of our present program.

obtained without the synergistic use of these drugs. This synergism is in line with the theory that the epileptic attack is a symptom complex and that there are more pharmacologic roads than one to its control.

Up to the present the total trend is remarkably favorable for the further reduction of seizures. On the basis of our experience we feel that in cases of epilepsy which do not yield totally to phenobarbital these two drugs should be used together. In fact, there is no reason why they should not be used together in every new case of epilepsy.

CORONARY OCCLUSION

A REPORT OF UNUSUAL ACTIVITIES AFTER RECOVERY

WILLIAM HALL LEWIS JR., M.D.

NEW YORK

There has been in recent years a better appreciation of the relation of structure and function of organs. In ascertaining the prognosis and the expectation of life for patients with heart disease, more emphasis is placed on the functional and less on the anatomic state of the heart and circulation. This change has been notable in the domain of valvular disease. The knowledge of the effects of coronary thrombosis is recent and is still being added to and revised. At first occlusion of a coronary artery was considered immediately and potentially dangerous to life. With more extensive observation there comes a realization that the prognosis must be suited to the degree of damage. The accepted mode of treatment requires restriction of physical activities and freedom from worry as far as possible, for the patient with angina pectoris or the patient who has suffered acute occlusion of a coronary artery is susceptible to other attacks, either fatal or incapacitating. In general it is considered that he should from choice, if not from necessity, forego unnecessary activities.

The exact demarcation between necessary and unnecessary activities is difficult to draw and even more difficult to maintain. To be occupied in a vocation entails exposure to the strains that go with the vocation and the necessary acceptance of activities that may be strenuous. The inescapable trend of such a course is evident in the life of the practicing physician. The vicissitudes of effort, of sleep, of hours of eating, of physical and mental strain are only too inherent in the conduct of a medical practice. To avoid them may mean failure to perform the full duties of, and perhaps therefore the necessity to resign from, the profession.

Probably more than other professional men, physicians suffer from cardiovascular disease, and especially coronary thrombosis. Those who have been afflicted must consider in the period of convalescence the question of retirement or of limited professional activity and its handicap. The issue is difficult to settle. Even as retirement is not desired or possible, so may it not be necessary. Return of physical capacity has often been beyond expectation. The personal records of others are salutary guide-posts. It is my purpose in this report to relate the unusual degree of recovery of a man who has had, so far, over five years of active endeavor after a severe acute attack of occlusion of a coronary artery.

This man has had an intimate experience with vicissitudes of coronary thrombosis. His brother died of

an acute occlusion at the age of 56, one year before the patient suffered his attack. His father died suddenly at 62 of heart disease. His mother-in-law died of a second attack three weeks after her first because, as he expressed it, she had been allowed to be too active. He has had many business acquaintances who have had the same affliction. He has a good understanding, because of his analytic and scientific aptitudes, of the pathologic processes involved in this disease. In the early period of his convalescence he was advised to continue his business career after careful trial of his capacity to meet its demands. With due care, exercised over a period of one year, he resumed and for a second year confined his activities mostly to his vocation. In the last few years, however, the scope of his business affairs has widened considerably. He has elected and been able to meet the increased demands without trouble; also, because of his active temperament, he has indulged in avocations of an unusual nature, to be described.

His original attack occurred Oct. 10, 1933, when he was 43 years of age; it was accompanied by severe substernal pain. During the three weeks before the acute attack there had been seven or eight periods of substernal discomfort, lasting several minutes, usually

Fig. 1.—The electrocardiograms with standard leads: A, taken Oct. 13, 1933, three days after the attack of coronary occlusion; B, taken December 4, three days before discharge from the hospital; C, taken April 15, 1939. The lead is designated to the left. Precordial leads were also taken; the tracings over the apical portion of the heart showed at first large upright T waves, which became smaller.

at the end of a day's work. His wife had been ill for three years with aplastic anemia, which had worried him considerably. He was indulging in athletics and leading an active, intense business life. His attack occurred during the forenoon. Electrocardiographic examination during the afternoon revealed early changes of coronary thrombosis. He was at home for three days. October 13 he was admitted to the hospital. At that time the temperature was elevated by 2 degrees. It gradually fell to normal by the tenth day. The white blood count was 16,000 cells per cubic millimeter on admission. Within one week it had fallen to the vicinity of 10,000, where it remained thereafter. The electrocardiographic changes were present in the standard second and third leads and in the precordial lead (fig. 1). Frequent records, including the precordial tracings over the front and the back of the chest, were taken. In one electrocardiogram premature contractions of ventricular origin were noted. The infarcted area was in the posterior aspect of the left ventricle. X-ray examination of the heart showed some decrease

in its size during convalescence. On admission the cardiac area was 136 sq. cm.; the transverse diameter was 15.2 cm., that of the lung fields 22.5 cm. (fig. 2). December 4, eight weeks later, the cardiac area was 125 sq. cm.; the diameter of the heart was 12.9 cm., that of the lung fields 26.5 cm. In the earlier film the right dome of the diaphragm was at the level of the eleventh rib posteriorly and in the later film at the tenth rib. Both films were taken with the patient supine in bed.

The regimen of convalescence was rigorously followed. It included seven weeks of complete rest in bed. The patient was discharged from the hospital December 7. He remained at home for one month, foregoing business but undertaking physical activity by gradually increasing walks. He then spent six weeks in Nassau, usually spending twelve hours of the twenty-four in bed and lying about on the beach in the morning; the mean pulse rate was 54 on waking in the morning and 60 at rest during the day. His subsequent activities may be described in his own words in a letter dated April 9, 1937:

Activities since January 1934 have been slowly but steadily increasing. The best measure of activity has been the amount of rest required in each twenty-four hours. The amount of rest in 1934 was about fifteen hours. This level has been reduced to a present average of about nine hours. Business activity has gone up, starting with zero activity in April 1934, steadily increasing until January 1937, when full normal business activity was resumed.

Smoking was dropped completely on hospitalization in 1933 and has never been started again; no coffee at any time; very weak tea irregularly; moderate alcohol irregularly.

Beginning in 1935 a great deal of flying has been done, both as passenger and as pilot, averaging perhaps 100 hours a year. The flying altitude was 3,000 to 5,000 feet, but a considerable amount of flying has been done at altitudes up to 15,000 feet.

The first skiing was in December 1935, with one week at Lake Placid at an elevation of 1,700 feet; in March 1936 there were two weeks at Arosa, Switzerland, at an elevation of 5,000 feet; in 1937 there were three days at St. Moritz at an elevation of 5,000 feet and one week at Zugspitze, Bavaria, at 8,000 feet. The altitude effect in skiing has been quite noticeable as quickened breathing. A further altitude effect was difficulty in getting any sound sleep, experienced at Arosa in 1936, but there was no difficulty whatever at the higher elevation in Zugspitze in 1937.

In addition to skiing, exercise has consisted in occasional swimming and regular dancing, averaging perhaps three to four hours weekly.

Beginning in 1935 green vegetables and fruit were substituted for a substantial part of the usual concentrated carbohydrate and protein foods; green vegetables were usually substituted for meat at one meal a day and fresh fruit for desserts at the main meals. There has been a very large consumption of oysters and clams, averaging perhaps half a dozen per day five days a week.¹

It seems that a marked increase in the feeling of well-being was coincident with the change in diet in 1935. Following each of the skiing holidays in 1936 and 1937 there was also marked increase in the feeling of well-being, gain in weight and reduction in the amount of sleep required. Now from seven and a half to eight and a half hours per night are adequate.

There has been on the average one European trip of about seven weeks' duration every six months since 1934. The trips have been in the main under de luxe conditions but with occasional hardships of travel, such as sleepless nights and limited diet.

The hardest physical exertion has been in skiing, which has been sometimes certainly heavier than was intended and gone nearly to the point of temporary exhaustion.

The death of his wife in June 1934, after a prolonged illness, entailed considerable worry.

His business life requires important decisions in one of the largest corporations in the United States. On his journeys in Europe, negotiations on a large scale have been made with foreign concerns. His business activities became more intense in 1937 and 1938, especially during the critical period in Europe in August and September of 1938 and likewise in 1939. A report dated Jan. 16, 1939, details the extent of these activities:

The regimen established in the beginning of the year 1937 was continued without change through that year and 1938, except that I had no opportunity to do any high altitude skiing during the winter of 1937-1938, owing to pressure of business.

My flying time as pilot has also been almost nil over the last two years for the same reason, but my flying time as

Fig. 2.—Size and shape of the heart, anteroposterior view, from a distance of 6 feet. The patient was lying supine for A, B and C and standing upright for C'. The dates are given in the legend for figure 1; C' was taken on the same day as C.

passenger has been if anything greater. I spent four months in Europe in two trips in the year 1937 and nearly five months in two trips in the year 1938. During these trips my average was perhaps three nights at a stretch in the same bed. Taking out twenty-one days at sea in each year, this would mean about twenty-five days or nights of travel a year in Europe, about half of which was by rail and the other half by air. In addition, each year there has been a fair amount of travel in the United States, including a transcontinental air trip each year. The trip in 1937 necessitated sitting up all night because the sleeper planes were not yet in use; the 1938 trip was in a sleeper plane. American transcontinental altitudes are in the range of from 6,000 to 12,000 feet. European altitudes are lower on the average, being from 3,000 to 8,000 feet, except in the Alps, where I have done very little traveling.

My principal reliance for exercise continues to be skiing and dancing, with supplementary gymnasium work, usually at sea. My weight has increased about 5 pounds during the last two years to the present level of 156 pounds. I usually gain 2 to 4 pounds during a European trip and lose most of it afterward.

1. This diet was selected by the patient.

His remarks following another European trip in March 1939 were:

My skiing holiday was reduced to four days at Kitzbuehl. The elevation of the town hotel was only 800 meters, but the principal skiing slopes are at an elevation of 1,800 meters. I had the usual amount of travel, including flying, but this is all now so much of a routine that I seldom think of it.

Examinations of the patient have been made at semi-annual and annual intervals since his acute illness nearly six years ago. The most recent ones were in November 1938 and April 1939, subsequent to European journeys. The electrocardiogram has presented the residual changes of myocardial infarction (fig. 1). The cardiac shadow has appeared normal in size and shape (fig. 2).

COMMENT

The history of this patient presents unusual features. There was no lack of cooperation during treatment of the acute state. There has been good understanding, on his part, of the nature of coronary thrombosis and its after-care. Flying in airplanes and even piloting a plane alone he has accomplished without trouble. He noted on one occasion while flying a plane across the White Mountains of New England at an altitude of 15,000 feet a slight quickening of respiration and a rise in the pulse rate from 72 to 84. Skiing at a high altitude involves presumably a double burden on the heart, yet he felt improved in strength at the time of his first residence in a high altitude. The history of the effects of coronary thrombosis is such, however, that natural improvement may have occurred at this time. He has been an active man for five and a half years since the original attack, certainly a long period of trial.

There are, no doubt, numerous personal records of unusual degrees of recovery from coronary thrombosis. Of published reports, letters of two English physicians are of interest. One, a consulting practitioner, not only resumed his professional life, with some changes, but indulged in seaside bathing, salmon fishing and skiing and skating in Switzerland.² The other, a surgeon, resumed surgical practice, operating up to three hours at a stretch; fond of sports, he indulged at first in cub hunting and later in riding to hounds.³ In both instances, as in the present case, the period of complete bed rest of from four to six weeks after the acute attack and the gradual resumption of activity in the succeeding five to six months were followed. These are the most important features of treatment.

SUMMARY

The history of a patient who suffered an attack of acute coronary thrombosis is considered noteworthy not because of the disease but because of the activities which the patient has been able to maintain, following very careful treatment for the acute condition. His business career was resumed on the basis of his capacity to meet its demands. The scope of the demands enlarged considerably and entailed a degree of activity beyond that advised and considered possible. In addition, because of his active temperament, flying at various altitudes up to 15,000 feet, dancing, swimming, and skiing each winter at altitudes up to 10,000 feet have all been accomplished apparently without detriment.

This report is published not to stimulate others who have suffered from coronary thrombosis to indulge in

unusual endeavor but to encourage them in expectation of being able to pursue normal activities without too severe restrictions. The range of activities can be gaged only according to the capacity of the individual.

NOTE.—Since this paper was submitted for publication, the patient has made a further unusual journey. He traveled by airplane (Pan-American Airways) to Europe on Aug. 16 and 17, 1939; the trip included nineteen hours of continuous flying from Port Washington, Long Island, to the Azores, and eleven hours of additional flying to Lisbon and Marseilles. The usual height flown on the southern Atlantic route is from 8,000 to 10,000 feet. He returned by airplane over the northern route on October 9 and 10, the journey from Foynes, Ireland, to New York taking about twenty-four hours. Although the flying height was usually 1,000 feet, part of this trip was very uncomfortable because of nausea due to rough weather.

An examination Oct. 20, 1939, six years after the original attack, requires no additional comment on the clinical, electrocardiographic and x-ray appearances.

Clinical Notes, Suggestions and New Instruments

DELAYED CUTANEOUS REACTION TO INTRA- DERMAL INJECTION OF BRUCELLERGEN IN BRUCELLOSIS

L. E. JANUARY, M.D., and JAMES A. GREENE, M.D., IOWA CITY

The cutaneous reaction following the intradermal injection of brucellergen is one of the diagnostic aids in brucellosis. The reaction, when positive, begins within twenty-four to thirty-six hours after injection and persists for more than forty-eight hours. The test is positive if, in addition to an area of erythema around the site of injection, there is also edema or induration which measures from 0.5 to 0.75 cm. or more in diameter. A delayed reaction, that is, one which does not begin until forty-eight hours or more after injection, is rare. It is for this reason that we are reporting a case in which the cutaneous reaction did not appear until the fourth day after the injection of brucellergen.

REPORT OF CASE

A farmer aged 43 entered the University Hospital July 10, 1938, because of headache, pain in the legs and fever. He had always enjoyed good health until December 1937, when he noted bloating of the abdomen after meals. The condition did not progress until three weeks later, when he was seized with severe pain in the lower back which radiated down the distribution of both sciatic nerves and forced him to bed. About the same time chills, fever and exhaustion appeared. These symptoms persisted with exacerbations and remissions until his admission to the hospital.

He consulted his physician about one week before admission, at which time a tentative diagnosis of brucellosis was made. Sulfanilamide was prescribed, and a severe persistent daily headache developed the following day. This symptom caused him to discontinue the drug and to come to the University Hospital. The history did not reveal the source of the Brucella infection.

The significant objective manifestations in this well developed and nourished man, who appeared acutely ill, were tenderness over both sciatic foramina, a temperature of 100.2 F., a pulse rate of 100 beats per minute, a leukocyte count of 13,200, a normal spinal fluid, a negative blood Wassermann reaction, repeatedly negative blood cultures and agglutination reactions for Brucella, a positive opsonocytaphagic index, and a trace of sulfanilamide in the blood.

One tenth cc. of brucellergen was injected intradermally into the left forearm on July 10. There was no reaction at the site of injection until the late afternoon of July 14. The

From the Department of Internal Medicine, State University of Iowa College of Medicine.

3. Coronary Thrombosis: The First Year After, correspondence, *Lancet* 1: 1472 (June 22) 1935.

following morning the area of erythema measured 4 cm. in diameter, and the central area of edema 1 by 1.5 cm. A second cutaneous test, made on the right forearm on the evening of July 14, resulted the next morning in an area of erythema 6 by 6 cm. in diameter with a central area of edema measuring 2 by 2.5 cm.

COMMENT

Huddleston¹ states that a delayed skin reaction in brucellosis is extremely rare. He has observed only two such instances. In both cases the specificity of the reaction was doubtful. Foshay,² on the other hand, thinks that the delayed reaction is not as rare as the literature indicates. He has seen such reactions in four or five cases of undoubted brucellosis. In his experience the reaction may be delayed as late as the seventh day, and such a delayed reaction is more likely to occur in the chronic than in the acute phase of the disease. That this type of reaction is rare in this clinic is illustrated by the fact that the diagnosis of brucellosis has been made in 160 cases during the past nine years, during which time only two such reactions have been observed. The other occurred in a parent of a patient in the Department of Pediatrics and was called to our attention by Dr. R. L. Jackson.³ We have been unable to find any report in the literature of a delayed skin reaction, as such, but Dr. Foshay states that he has seen it mentioned in the general literature on brucellosis.

The cause for the delayed reaction is not clear. The administration of sulfanilamide to our patient just prior to the test raised the question whether or not this drug prolonged the time of appearance of the reaction. That not all delayed reactions are due to this drug is shown by the experience of Huddleston, Foshay and Jackson, whose patients did not receive sulfanilamide. Furthermore, our own experience makes it doubtful whether sulfanilamide will produce a delay in the cutaneous reaction in brucellosis. We have administered the drug for periods of from two to five days to two patients who previously had shown positive cutaneous tests without alteration of the time of appearance of the reaction. A third patient receiving the drug at the time of admission did not show a delayed reaction. The last patient had not had a previous cutaneous test with brucellergen.

Council on Pharmacy and Chemistry

REPORTS OF THE COUNCIL

THE COUNCIL HAS AUTHORIZED PUBLICATION OF THE FOLLOWING REPORTS.
PAUL NICHOLAS LEECH, Secretary.

THE PRESENT STATUS OF THERAPY WITH CHORIONIC GONADOTROPIN

The gonadotropic substance from the urine of pregnancy has been available for clinical use for nine years. Although it was enthusiastically received by physicians and placed in extensive therapeutic use, there has always remained a certain amount of skepticism as to its value. The following report contains a summary of the experiences with this substance in the clinic up to the present time with an evaluation of the results reported.

When the gonadotropic activity of pregnancy urine was first demonstrated by Zondek, it was considered that the responsible substance was secreted by the anterior pituitary. In rodents, pregnancy urine, or certain extracts thereof, induced follicular growth and corpus luteum formation. At the time, the concept was advanced that this gonadotropin consisted of two hormones—prolan A, the follicle stimulating hormone, and prolan B, the luteinizing hormone—on the basis of its effect in the rat, mouse and rabbit. Further experimentation has, however, revealed that this substance is a single entity and not composed of two factors, that it arises from the placenta rather than from the pituitary and that it differs fundamentally from the gonadotropins of the anterior lobe.

One of the most significant differences in its physiologic reactions from anterior lobe preparations is its inability to stimulate

to any appreciable extent the ovary of the monkey or the human being. Injection of chorionic gonadotropin into primates will not induce follicular growth or corpus luteum formation. On the contrary, reliable investigators have observed definite degenerative changes in the ovaries of women and monkeys treated with this substance. In addition, no clearcut endometrial responses have been observed in primates treated in this manner, which indicates conclusively the inability of this substance to stimulate the growth of normal ovarian structures.

The physiologic action of chorionic gonadotropin is not limited to the female, but it exerts a definite effect on the male reproductive organs. It is generally agreed that this substance acts on the interstitial cells of the testes, causing them to elaborate the androgenic hormone of the testis, which in turn induces growth of the accessory sex organs. This substance is effective in male monkeys and human beings. Among the reactions induced in the monkey is the descent of the testes in the prepubertal animal. In some animals there may be some increase in size of the semeniferous tubules, but there is little if any effect on the germinal epithelium. Spermatogenesis is, however, maintained by chorionic gonadotropin in recently hypophysectomized rats, but it is not restored after atrophy or induced in normal immature rats.

The therapeutic application of chorionic gonadotropin has covered a wide range of conditions. Many of the trials have been on an unsound or improperly conceived basis. Its use in the treatment of ovarian disturbance, for example, has no scientific rationale at the present time, although when first introduced for the treatment of these dysfunctions the physiologic basis for therapy appeared excellent.

First, Novak and Hurd¹ reported gratifying results in the treatment of functional menorrhagia with chorionic gonadotropin. They based their treatment on the concept that excessive menstrual flow of functional origin resulted from the lack of an active corpus luteum in the ovary. Thus the ovarian estrogen was unopposed by progesterone, the hormone of the corpus luteum, with consequent uterine hemorrhage. Chorionic gonadotropin was therefore administered in an attempt to induce the formation of a corpus luteum in the patient. The reported successful results were ascribed to this response. It developed shortly afterward that this substance has little or no ability to luteinize the human ovary. Novak² has since admitted the lack of a suitable explanation for the therapeutic responses which he obtained in such cases, although he still maintains that good results are obtained. It might be mentioned at this point that functional uterine bleeding is frequently found in the presence of a secretory endometrium, which indicates an active corpus luteum in these cases. The rationale of unopposed estrogen originally advanced for the use of chorionic gonadotropin in menorrhagia is therefore without basis in many instances.

By far the most common type of ovarian dysfunction treated with this substance is uterine bleeding. As mentioned previously, a satisfactory rationale for the treatment in this condition is lacking. There have been published, however, a great many reports dealing with such therapy. Some of these reports favor enthusiastically the use of chorionic gonadotropin in bleeding cases while others are equally pessimistic. It is difficult to discount the results of many investigators, but at the same time the failure to obtain such results by others cannot be disregarded. A recent review by Jeffcoate³ analyzes thoroughly the literature up to 1937. Jeffcoate combined a summary of the published data with the results of a questionnaire which he submitted to a number of clinicians in Europe. The following quotations indicate much of Jeffcoate's evaluation of this therapy:

"Results Collected from Literature.—The collection of published results is associated with many difficulties. The number of communications dealing with organotherapy is immense, but the number of recorded cases is comparatively small. Many authors mention that they have treated several hundreds of patients successfully, but they make no attempt to give details, and others base their conclusions on isolated cases. Extravagant claims, unaccompanied by clinical notes, are common and create the impression that they are handed on as unverified statements from one

writer to another. After a close search and excluding articles in which not more than two cases are described, records (and some of these are very incomplete) of only 594 cases have been traced. Comparison of individual statistics is not always easy, since different commercial preparations are used by different observers; some series of cases are grouped on a pathological, others on a clinical, basis, while many are presented without any attempt at classification. Moreover, the after-histories of the cases described are frequently omitted.

"Control of Bleeding.—Consideration of table I reveals extraordinary variations in results. The percentage of cures varies from 100 to 28 and is 69 for the whole series. Some writers are much impressed with this method of treatment while others consider it almost useless. There is a suggestion in recent reports that others have noticed this lack of uniformity in results.

"In this connection, inquiry into the details of recorded cases shows that individual criteria of success vary, and many patients described by a particular writer as being cured would be viewed by another observer as showing no response to treatment. Moreover, the estimation of results is always clouded by the fact that functional uterine hemorrhage is a condition which is likely to cease spontaneously, and it is impossible to control results except by amassing large numbers of cases.

"Other factors contributing to the variation in results are the differences in the individual techniques and dosage and the inconsistent potency of the preparations used, as emphasized by Novak and Hurd. Nevertheless, it is likely that the total figures of reported results, as presented here, give a more accurate conception of the value of the treatment than do the claims of individual writers each basing his conclusions on small numbers of cases."

"The opinions expressed in reply to the questionnaire (tables IX and X) are illuminating and provide the final and conclusive proof that this form of treatment does not satisfy the claims which hitherto have been made for it. Of twenty-seven authorities using gonadotropic hormones, only five report consistently good results (in specially chosen patients), fourteen note poor or fair response, and two of these, Maguire, Plass, and one, Stander, believe that all the so-called cures are merely spontaneous and in no way connected with the treatment. From these figures the only possible conclusion is that clinicians in general are coming to regard even this type of organotherapy as being unreliable, and although it may produce some brilliant results, it is by no means rare to see patients who show no response to it."

The response of such cases to chorionic gonadotropin is often temporary. According to Jeffcoate:

"Although it is frequently stated that the advantage which the use of gonadotropic hormones has over other methods of treatment such as curettage or even the administration of corpus luteum is that the ordered ovarian cycle is permanently corrected, the statistics presented in the accompanying tables provide no confirmation of this. On the contrary, the high proportion of cases which relapse is a clear indication that the success of treatment is purely temporary. Novak, who in 1931 professed himself unable to say whether the results were permanent, now asserts that the effect applies only to the particular attack of hemorrhage for which organotherapy is instituted. Neumann and Meigs also conform to this opinion. The replies to the questionnaire provide further confirmation of this view; there are no observers who say that gonadotropic hormone therapy is consistently permanent in its effects, two say it is probably permanent, and a third that it produces permanent cures in pubescent cases only; the remaining twenty-one replies (88 per cent) indicate that it is purely temporary in action or very variable in its remote effects. It would seem that the subsequent menstrual history of most patients resembles that of those who receive no hormonal treatment for this disorder. All these cases of functional uterine hemorrhage have a distinct possibility of a spontaneous recovery, but there is, in all, a tendency to a recurrence of hemorrhage or periods of amenorrhea. It may be that the more frequent and more rapid occurrence of relapses in menopausal patients explains why this form of treatment is apparently of less value in their cases than it is in the control of anovular hemorrhage in early life."

Few clinical reports have appeared since 1937. Novak in 1938 wrote that "in a considerable proportion of cases the bleeding is checked or improved though in many others it is not." Mazer,⁴ who at one time wrote optimistically that chorionic gonadotropin was "almost a specific in the treatment of functional uterine bleeding of puberty and maturity," has altered his views somewhat. He believes now that there is a "cure" in 60 per cent of dysfunctional bleeding in the child bearing age, but it is far less effective in pubertal or menopausal bleeding. Hamblen⁵ has recently reviewed the therapeutics of gonadotropic substances in ovarian disorders. His conclusions reflect the uncertainty of this therapy:

"Consideration of the clinical data available indicates that there exists little definite proof that therapeutic efficiency has been established for the gonadotropes in most supposed endocrinopathic gynecology."

There seems little doubt that the early enthusiasm is shared by fewer investigators at the present time. The skepticism of many as to its value in bleeding cases is nurtured by the lack of a sound physiologic basis for such therapy. In the first place, the causes of these conditions have not been demonstrated and, in the second, the ability of chorionic gonadotropin to induce appropriate ovarian changes seems most doubtful.

The possibility of ovarian damage by this therapy has been discussed by various investigators. It is commonly noted that patients develop periods of six to nine months amenorrhea after the therapy, which is interpreted frequently as a temporary arrest of ovarian function. Likewise, the occurrence of an increase in menstrual flow immediately after the first or second injection has been suggested as being due to a sudden drop in estrin threshold due to inhibition of ovarian activity. The consensus is, however, that little permanent damage is inflicted by chorionic gonadotropin.

There are numerous other ovarian conditions in which chorionic gonadotropin has been tried, such as amenorrhea, dysmenorrhea and sterility. Most of this work is fragmentary or inadequately confirmed. The lack of data justifies the conclusion that the claims for the use of chorionic gonadotropin in these ovarian disturbances are unwarranted.

CRYPTORCHIDISM

By far the greatest use for chorionic gonadotropin therapy has been in the treatment of disturbances of the male sex organs. A large number of investigators have reported successful treatment with it in cryptorchidism and in hypogonadal states. Data have been presented which ordinarily would firmly establish this treatment in cryptorchidism as reliable and consistently beneficial. In the past year or two, however, a certain amount of doubt has developed as to the value of this therapy and the entire problem has been reopened to considerable questioning. Engle showed that chorionic gonadotropin was capable of inducing descent of the testes in immature monkeys. Shapiro⁶ was first to demonstrate that similar results could be obtained in cryptorchid boys. This work was soon confirmed by many others, and it became more or less accepted that this therapy was indicated in all cases of cryptorchidism unless there was some form of anatomic lesion preventing the descent of the testes into the scrotum.

In spite of the general accord with which this therapy was held, a discrepant note was later interjected by several investigators. Thompson⁷ and others have repeatedly failed to obtain the high percentage of successful results reported by other workers. They were able to induce descent in only 20 per cent of fifty undescended testes compared to about 60 per cent of 860 undescended testes reported in the literature. They attribute this difference in results to the fact that there was excluded from their treatment all testes of the migratory type—those which can be readily manipulated into the scrotum. This type of testis was classified as pseudocryptorchidism, which has been described by Hamilton. Gentle handling, warmth and relaxation will often relieve the cremasteric spasm and bring the testes into the scrotum. It seems quite likely that many such cases have been included in series which were treated with chorionic gonadotropin. Those cases in which descent was induced within a few hours or days are undoubtedly pseudocryptorchids.

The conviction is growing that testes which descend after hormonal therapy are those which would descend without treatment at puberty. Apparently the mechanism of descent is the elaboration of testicular hormone spontaneously at puberty or induced by gonadotropic hormone administration before puberty. Johnson⁸ has recently called attention to the fact that of 1,000 boys examined in a routine manner seventeen were cryptorchid but that there were only two adults in 1,000 with this condition. He believed it conclusive, on these grounds, that fifteen of the original seventeen in 1,000 had had spontaneous descent. Thompson and his associates likewise have questioned the value of chorionic gonadotropin therapy for descent of the testes if it does no more than produce a descent at an earlier age than at which there would be a natural cure. According to these authors:

"The crux of the problem is whether a testis made to descend at an early age with treatment is more likely to be normal than one which descends later without treatment. The consensus appears to be that in

true cryptorchidism the testis should be brought into the scrotum at an early age, although there is some difference of opinion on this point. Treatment with this material, by distinguishing between those cases in which descent is prevented by anatomic factors and those in which it is not, makes it possible to tell early what patients will require surgical intervention. However, it should be pointed out that little is known about the effect of premature stimulation with this material on the function of the testis after puberty."

In their opinion, the puberty hormonal treatment of this condition should not be accepted without question:

"In the light of these observations it is important to maintain an open mind on the treatment of undescended testes with the anterior pituitary-like principle. Many reports appear to be overenthusiastic. If the importance of bringing the testis into the scrotum at the earliest possible age has not been overestimated, perhaps the wisest course is to administer this material cautiously and carry out operative procedures if descent fails to occur."

An analysis of the results and more recent trends in such therapy reveals that (1) cures are not as frequent as reported in the early literature, which undoubtedly included many cases of pseudocryptorchidism, (2) most cases which respond to such therapy would descend spontaneously at puberty, (3) those cases which do not respond to this therapy require surgery, and surgery at an early age is desirable, and (4) such therapy reveals usually whether or not the testes will descend spontaneously without waiting until puberty arrives. It also claimed that endocrine therapy aids in the surgical treatment of undescended testes, either preoperatively or postoperatively. It may therefore be concluded that, although the early optimism is unwarranted, gonadotropic therapy is of value in cryptorchidism if the limitations of such therapy are understood by the physician.

The untoward or toxic effects have been chiefly confined to an occasional inflammatory reaction and pain at the site of injection or an occasional mild febrile reaction. Precocious puberty with enlargement of the genitals is a more serious type of undesirable reaction in boys under treatment. This occurs usually after long continued administration at a relatively high dosage. Besides the dangers of psychic disturbances, there exists the possibility of affecting the growth of long bones by this premature aging under the influence of the male sex hormone elaborated by the testes. In order to avoid the risk of excessive testicular stimulation, it is advisable to limit the administration of chorionic gonadotropin to from six to eight weeks. If there are no signs of descent by this time, there is slight chance of its occurring.

In addition to this danger, it has been shown that long continued administration may lead to inflammatory changes and adhesion about the retained testes which may interfere with surgical procedures.⁹ These observations have not been confirmed as yet.

HYPOGONADISM

The condition which is most often associated with hypogonadal activity is the so-called Frölich's syndrome. The diagnosis of disturbance is quite frequently made, usually on the basis of fat distribution and small genitalia. Most of these patients, however, respond to diet alone and after puberty develop in a normal manner sexually. The diagnosis of hypogonadism or Frölich's syndrome in boys should be made with reserve and the endocrine treatment should accordingly be avoided. After the normal age of puberty, however, hypogonadism can be more readily diagnosed and treatment may then be instituted.

The few reports in the literature indicate that adult patients who failed to mature sexually may respond to chorionic gonadotropin. The genitals enlarge and masculine characteristics develop. This therapy is temporary, however, and the changes regress as soon as the therapy is stopped. The data published on the results with this therapy are as yet inadequate as a basis on which final conclusions can be drawn.

SPERMATOGENESIS

Several investigators have reported the use of chorionic gonadotropin in sterility. Their studies are rather incomplete. Brosius and Schaffer¹⁰ have reported the induction of spermatogenesis with such therapy in a case of azoospermia. Heckel¹¹ has treated eight sterile males with this substance, after which

the wives of two became pregnant. Rubinstein¹² claims that the sperm counts increased following such therapy. His results are statistically unconvincing. On the other hand, McCahey¹³ was unable to demonstrate any increase in the sperm count after injection of chorionic gonadotropin. Many other urologists have been disappointed in its use in sterility. The physiologic response of this substance in experimental animals would not lead one to anticipate much of an effect on spermatogenesis, since it is well known that this substance influences chiefly the interstitial cells and has little if any effect on the germinative epithelium. It is therefore apparent that deficient sperm formation is a doubtful indication for such therapy on both clinical and experimental evidence.

OTHER REPORTED USES

Many conditions have been suggested for the use of chorionic gonadotropin. Acne, the eternal target of every new endocrine preparation, has received considerable attention. Except for isolated enthusiastic reports, the results have not been found encouraging.¹⁴ Other conditions which have been mentioned for this therapy include enuresis, migraine and peripheral vascular disease, but adequate evidence in support of such therapeutic claims is still lacking.

CONCLUSIONS

Among the conditions for which chorionic gonadotropin is recommended are functional uterine bleeding, cryptorchidism, hypogonitism, amenorrhea, oligomenorrhea and enuresis. In accordance with the more recent developments in this therapy the Council is unable to endorse many of these recommendations. The Council believes that such therapy is of definite value in functional cryptorchidism within the limitations discussed previously in this report. Although a considerable amount of data has been published on the treatment of uterine bleeding, the Council considers this therapy still unproved. Such treatment of other ovarian disturbances appears practically of little value. Until further evidence will have been made available, the Council approves of this treatment for cryptorchidism but considers such therapy of functional uterine bleeding as still being in the experimental stage. Likewise the treatment of male hypogonadism is also considered experimental. The Council approves of no other indications for such therapy at the present time.

THE FOLLOWING REPORT ON NOMENCLATURE WAS ADOPTED BY THE COUNCIL BUT WAS WITHHELD FROM PUBLICATION BECAUSE THE COUNCIL WAS CONSIDERING ACCEPTANCE OF THE DRUG, WHEN IT COULD BE PUBLISHED SIMULTANEOUSLY WITH THE DESCRIPTION OF THE LATTER. SINCE IT DOES NOT SEEM PROBABLE THAT THE DRUG WILL BE ACCEPTED IN THE NEAR FUTURE, IT WAS THOUGHT ADVISABLE TO RELEASE THE REPORT.

PAUL NICHOLAS LEECH, Secretary.

NEOPRONTOSIL (FORMERLY PRONTOSIL)—AZOSULFAMIDE

The term "Prontosil" has been used both abroad and in this country to denote a number of substances. The Council informed the Winthrop Chemical Company that it could not recognize the term "Prontosil." The firm stated that it would be willing to adopt the term "Neoprontosil" for the substance formerly known as 4-sulfonamide benzene-2-azo-1-hydroxy-7-acetyl amino naphthalene-3:6-disodium sulfonate. The firm inquired whether the Council would be willing to accept the name "Azosulfanil" as the nonproprietary descriptive name for this product, but it was the opinion of the Council that this term might be misleading, since it carried apparently incorrect implication as to the structure of the compound. The Council voted that Neoprontosil be recognized as the Winthrop proprietary name for the product 4-sulfonamide benzene-2-azo-1-hydroxy-7-acetyl amino naphthalene-3:6-disodium sulfonate, and that Azosulfamide be recognized as the descriptive nonproprietary name for this substance.

The Council points out, however, that the product "Neoprontosil" does not stand accepted for inclusion in New and Non-official Remedies because the firm, to date, has not made the product acceptable.

SATURDAY, FEBRUARY 10, 1940

THE PLATFORM OF THE AMERICAN MEDICAL ASSOCIATION

The American Medical Association advocates:

1. The establishment of an agency of the federal government under which shall be coordinated and administered all medical and health functions of the federal government exclusive of those of the Army and Navy.
2. The allotment of such funds as the Congress may make available to any state in actual need, for the prevention of disease, the promotion of health and the care of the sick on proof of such need.
3. The principle that the care of the public health and the provision of medical service to the sick is primarily a local responsibility.
4. The development of a mechanism for meeting the needs of expansion of preventive medical services with local determination of needs and local control of administration.
5. The extension of medical care for the indigent and the medically indigent with local determination of needs and local control of administration.
6. In the extension of medical services to all the people, the utmost utilization of qualified medical and hospital facilities already established.
7. The continued development of the private practice of medicine, subject to such changes as may be necessary to maintain the quality of medical services and to increase their availability.
8. Expansion of public health and medical services consistent with the American system of democracy.

THE NEW WAGNER HOSPITAL BILL

Elsewhere in this issue appear a statement sent by the President to Congress relative to his plans for the building of hospitals and also a transcript of a bill, S. 3230, introduced by Mr. Wagner in the Senate of the United States on February 1. Here is a new pattern not observable in other medical or hospital legislation introduced in recent years. This measure provides for assisting state, county, health and hospital districts or other political subdivisions; thus it recognizes the local character of most problems in medical service. The total sum involved is relatively small, indicating the experimental nature of the proposal. The third section indicates that communities applying for such hospitals must establish the existence of need. Moreover, these hospitals are to be available to all groups of the population.

Especially significant is section 4, which establishes a national advisory council to consist of six members, who

shall be selected from leading medical or scientific authorities outstanding in matters pertaining to hospitals and other public health services. These six members are to be appointed by the Surgeon General with the approval of the Federal Security Administrator. These offices are largely honorary, since the compensation is \$25 a day and expenses. Their services are wholly advisory, but obviously their opinions are likely to have considerable weight with the officials primarily responsible for carrying out the work. Indeed, the advisory council is charged with considering and recommending to the Surgeon General all applications for funds for building hospitals. It is to formulate standards, review reports and make inspections relative to professional services and the standard of maintenance of the hospital. In this connection the Surgeon General is also authorized, after consultation with the council, to study needs for hospitalization and problems of hospital operation, to approve projects in the hospital field, to provide for training and instruction of personnel, to make inspection and reports on professional services, and to safeguard the quality of service.

The hospitals are to be leased to the communities in which they are established, the only consideration for the lease being the maintenance and operation of the hospital in accordance with the provisions of the act. It is indicated that the lease may be terminated by the Surgeon General on six months' notice if the hospital fails to comply with the provisions of the act. Apparently nothing is said as to what will be done with a hospital in case the lease is terminated.

In section 10, hospitals are authorized to include physical facilities necessary not only for the prevention and diagnosis or treatment of disease but also for protection of the public health. Thus it becomes possible to establish health protecting agencies within the structure of the hospital. The divergence of opinions on the desirability of this integration of public preventive medical services into private or community hospitals demands careful consideration before the final wording is determined.

Coincidentally, Senator Mead, of New York, introduced into the Senate his bill, S. 3246, to authorize loans for hospitals, water, sewers, stream pollution control, and related projects and facilities. This bill proposes to authorize a federal appropriation of \$300,000,000 for the projects mentioned. It defines a hospital as any institution or facilities for treating illness or disease, including any health, diagnostic or treatment center, station, institution or clinic. This bill also states that not to exceed \$100,000,000 be devoted to the hospital projects. This bill has been referred to the Senate Committee on Banking and Currency, of which Senator Wagner is chairman.

The Wagner bill was also introduced into the House of Representatives on January 31 by Mr. Lea and referred in that body to the Committee on Interstate and Foreign Commerce. It would seem to any casual

observer that only one of these bills is needed to accomplish the President's purpose, and that therefore the Wagner bill is the one likely to have much consideration, rather than the Mead bill.

Obviously this bill, if enacted, will place a tremendous responsibility on the Surgeon General of the United States Public Health Service and the Federal Security Administrator. The location and conduct of these new medical institutions is a matter which will concern greatly not only the public but particularly the medical profession and all who work in the field of the hospital. Perhaps, therefore, it might be better to assign a little larger share of responsibility and control to the Advisory Council. Moreover, the language of the act is somewhat confusing in that certain phrases fail to specify clearly the fact that these clauses apply only to the hospitals to be built under the act and do not concern inspection, training of personnel, or control of hospitals and medical services generally.

THE COUNCIL ON PHARMACY AND CHEMISTRY COMPLETES THIRTY- FIVE YEARS OF SERVICE

Thirty-five years has passed since the Council on Pharmacy and Chemistry met at Pittsburgh to organize. Since that time its work as a standing committee of the Board of Trustees of the American Medical Association has been continuous. In 1905 the exploitation and advertising of drugs to physicians were "misleading," "mendacious," "execrable." Shortly after formation of the Council the Food and Drug Act of 1906 was passed by Congress. Probably at that time some felt that the passing of that law made the work of the Council unnecessary.

First the Council exposed the most egregious of the deceptions practiced on the medical profession. Then came the more serious task of passing on proprietary drugs detailed to the medical profession. Products which complied with the rules were listed in the column of *THE JOURNAL* called New and Nonofficial Remedies. The first issues of New and Nonofficial Remedies were printed as supplements to *THE JOURNAL* but soon it became evident that the material would be too voluminous for such use. In 1907 appeared a volume entitled Reprints of New and Nonofficial Remedies, including reprints from *THE JOURNAL* of articles tentatively accepted by the Council on Pharmacy and Chemistry. It contained 112 pages and included 230 products. The first issue of New and Nonofficial Remedies as a book, which has been the prototype of all subsequent annual volumes of this book, was that of 1909, consisting of 147 pages of descriptions of products. The latest volume of New and Nonofficial Remedies (1939) contained 531 pages, exclusive of the various indexes, and is printed in much smaller type than that of 1909.

From the time of its organization the names of the members of the Council and their connections have been made known; members, with the exception of the

executive secretary, serve without remuneration. The Council publishes its conclusions, whether they were for or against the acceptance of a drug. It issues reports to the medical profession on matters of materia medica. Products are admitted according to a set of rules published for the information of physicians and manufacturers. Remuneration in any form is never accepted for the consideration of submitted preparations. Of the original membership¹ in the Council two have served continuously during this period—Professor Emeritus Robert A. Hatcher, of Cornell University Medical College, and Dean Torald Sollmann, of Western Reserve University School of Medicine. The Council still publishes its reports almost weekly in the columns of *THE JOURNAL*, both on the rejection and on the acceptance of various drug preparations. In addition it publishes statements on the status of new drugs. In 1939 reports on the status of drugs included those on sulfapyridine, chorionic gonadotropin, vitamin K, testosterone propionate, the promiscuous use of barbital compounds, sobisminol mass and sobisminol solution, cyclopropane, vitamins, local anesthetics, dilantin sodium, picrotoxin and stilbestrol.

The rules now governing the acceptance or rejection of remedies are practically the same as those adopted in 1905. The interpretation of the rules, however, has been amplified and clarified to meet new conditions. An additional rule was adopted about fifteen years ago to the effect that concerns whose policies were contrary to scientific medicine and inimical to the best interests of the public and the medical profession would not be recognized by the Council. Now, in 1940, the situation as far as the consideration of drugs is concerned is vastly improved, owing largely to the efforts of the Council, with the militant aid of *THE JOURNAL*. Advertising claims employed by manufacturers of pharmaceuticals for products accepted by the Council have, in the main, attained standards of accurateness and truthfulness not found in any other field of marketing or in the entire medical world outside the United States. In fact, physicians look askance at journals which accept advertising of non-Council accepted products. More and more physicians ask detail men whether or not their proprietary products have been accepted by the Council and if not, why not. Now a new Food, Drug and Cosmetic Act has just become effective, and again some suggest that there may be little need for the Council on Pharmacy and Chemistry. The new Food, Drug and Cosmetic Act has been a decided advance, but mainly in the field of drugs sold for self medication or, as currently termed, for "over the counter" sales. The licensing bill for new drugs is intended to determine the harmfulness of the drug. Congress did not give the Food and Drug Administration power to determine

1. The original members of the Council were Arthur R. Cushny,* C. Lewis Diehl,* C. S. N. Hallberg,* Robert A. Hatcher, L. F. Kebler, J. H. Long,* F. G. Novy, W. A. Puckner,* Samuel P. Sadtler,* J. O. Schlotterbeck,* George H. Simmons,* Torald Sollmann, Julius Stieglitz,* M. I. Wilbert* and H. W. Wiley.* Those whose names are followed by an asterisk are deceased.

whether or not a drug is a worth while addition to *materia medica*. Congress, in enacting the Wheeler-Lea Act and the Food, Drug and Cosmetic Act, has also realized the necessity of expert medical opinion. More and more, no doubt, the opinions of the Council will increase in importance. Those firms which have been following the leadership of the Council have already found that it is much easier to comply with the new Food, Drug and Cosmetic Act and the Wheeler-Lea Act in the case of their accepted medicaments than have some firms which have tried to ignore the Council by extolling nonaccepted preparations.

The Board of Trustees has increased frequently the personnel of the headquarters staff,² which carries out the executive work. The unselfish service of the Council members and the accomplishments of the Council merit the unfailing continued support of the medical profession.

HEALTH AT THE NEW YORK FAIR IN 1940

The announcement, just released, that the Medicine and Public Health Building at the New York World's Fair will reopen for the 1940 season on May 11 under the direction of the American Museum of Health is gratifying. Undertaken last year as an idealistic experiment, the medical and public health exhibits at the New York World's Fair enter the new season with a background of proved success. More than 7,500,000 visitors were clocked in a daily check on attendance. This breaks the record in the field previously held by the International Hygiene Exposition in Dresden in 1911 with 5,500,000. Every third World's Fair visitor came to see these exhibits, demonstrating the intense interest of people in their health even in competition with extravagant presentations of industrial enterprises.

In assuming direction of the medical and public health exhibits the American Museum of Health will maintain the same policy that guided the planning of the exhibits last season. With the backing and cooperation of the medical profession, each exhibit will present with scientific accuracy the important fundamentals and noteworthy developments in medical science. There will be no exploitation of commercial products or organizations. The ethical pharmaceutical houses and non-commercial organizations which participated in the 1939 exhibit have expressed their willingness to continue their exhibits under this policy, which brought them so much public good will.

More than one and a quarter million dollars was expended in the presentation last year. Although it was designed primarily for the general public, professional visitors last year found many points of interest. Among

them were such exhibits as those on allergy, the pneumonia exhibit demonstrating serum therapy and sulfa-pyridine, the scientific exhibit of the Rockefeller Institute on the newest discoveries in the virus field, the famous Carrel-Lindbergh method of maintaining life in entire organs when outside the body, and the introduction to such new diseases as equine encephalomyelitis. Of interest to the general public, professional visitors and especially medical students was the effective exhibit on medical education, sponsored by the American Medical Association. One of the best attended exhibits in the Hall of Medical Science, this exhibit presented a concise yet comprehensive picture of the varied elements in a medical education and the high standards in medical training prevalent in this country. The Association was responsible also for another popular feature: the decorative and educational murals on the main aisle in this hall. These murals, depicting the history of the advancement of medical science, were financed by the Association and executed by artists of the Federal Art Project. Members of the American Medical Association should plan definitely to visit the Medicine and Public Health Building during the annual session of the Association to be held this year in New York.

Current Comment

ALLOTMENT OF FEDERAL FUNDS FOR PUBLIC HEALTH SERVICES

The Surgeon General of the United States Public Health Service, with the approval of the Federal Security Administrator, has recently revised the regulations under which federal funds authorized by the Social Security Act for establishing and maintaining adequate public health services are to be distributed for the fiscal year 1940.¹ Allotments amounting to 29.1 per cent of the available appropriations will be made to the several states in the ratio which the population of each state bears to the population of the United States as shown by the Census Bureau 1937 midyear population estimates. Allotments amounting to 41.8 per cent of available appropriations will be made to the several states on the basis of (1) the ratio which the mean annual number of deaths in each state from pneumonia, cancer and other infectious and parasitic diseases, except influenza and syphilis, bears to the total mortality from these causes in the United States as shown by the Bureau of Census Mortality Statistics for the four years 1931-1934; (2) prevalence of malaria, hookworm disease, trachoma, typhus fever and similar geographically limited diseases, special industrial hazards and other conditions that result in an inequality of exposure to these hazards among the states; (3) special conditions which create unequal burdens in the administration of equal public health services among the states indicated by the relative per capita cost of the operation and maintenance of state governmental services as shown by the Statistical Abstract of the Depart-

2. Physicians may be interested to know that this staff consists of eight men and twelve women. In addition, the A. M. A. Chemical Laboratory, composed of four Ph.D. chemists, besides the director and two assistants, devotes most of its time to the work of the Council. The membership of the Council consists of eighteen individuals. The Council carries on its work by means of a weekly bulletin containing from fifty to a hundred pages, and the members all return their votes and comments within a week after they have been received.

ment of Commerce for the years 1929-1933, and (4) the need for regional training centers. Allotments amounting to 29.1 per cent of available appropriations will be made to the several states on the basis of the financial needs of such states, "which is determined to be the ability of the state to raise revenue expressed indirectly in terms of differences in per capita five year mean income as computed by the National Industrial Conference Board." To be eligible to receive any of these federal funds, a state must submit a comprehensive statement of the state health organization, programs, appropriations and budgets, including all the activities maintained through local, state or federal funds under the supervision of or in cooperation with the state department of health. A state also must submit and have approved a proposed plan for extending and improving the administrative functions of the state department of health, including a state plan for a merit system of personnel administration and a proposed plan for extending and improving county, district and city health services. Except as revised by the new regulations, the regulations promulgated by the Surgeon General May 23, 1939,² for the distribution of federal funds for public health services, remain in effect. There would seem to be here an attempt toward appropriation where need exists and where trained personnel are available.

THE RELATION OF BRUCELLOSIS TO HODGKIN'S DISEASE

Recent observations by Parsons, Poston and Wise,¹ of the departments of pathology and bacteriology of Duke University, direct attention to the relation between chronic brucellosis and Hodgkin's disease. Only reports of a more or less preliminary nature are available; nevertheless these present the question clearly. In the cases studied the morphologic changes were characteristic of Hodgkin's disease, while *Brucella* (porcine or bovine) was obtained in cultures taken of the enlarged glands and in the one fatal case also of other structures. The cases may be spoken of as instances of "chronic brucellosis which presented a clinical and histologic picture strikingly similar to that of Hodgkin's disease." The microscopic changes include complete destruction of the normal architecture of lymph nodes, eosinophilia, areas of fibrosis and production of large, pale mononuclear cells as well as of giant cells of the Dorothy Reed or Sternberg type. The problem is presented whether this type of reaction can be caused by chronic brucella infection, that is to say whether Hodgkin's disease as the term now is used includes manifestations of chronic glandular brucellosis. This and related problems demand and no doubt will be subjected to further investigation in various places. Here it may be noted now that, while cultures of the lymph nodes studied by the Duke observers yielded *Brucella*, the serum of the patients concerned did not agglutinate *Brucella*. Other immune tests also were negative. The importance of this observation is a matter for future determination but it may be of fundamental as well as practical sig-

nificance. It appears that in certain forms of chronic brucellosis negative immune reactions do not exclude brucella infection; also that in cases diagnosed clinically as Hodgkin's disease microscopic examination may not tell the whole story—competent brucella cultural studies will be needed whatever the relation of brucellosis to Hodgkin's disease eventually is determined to be. The work under consideration is certain to create a new interest in chronic brucellosis and in Hodgkin's disease which there is good reason to hope may lead to a better understanding of the nature of chronic infectious granulomatous processes.

DIETARY IMMUNITY

Resistance to toxic or infectious agents apparently varies with nutritional conditions. According to Holt and Meyer,¹ of the Department of Pediatrics of Johns Hopkins University, this nutritional variation in toxin resistance is relatively specific, a diet increasing resistance against one toxic agent, for example, causing no change in resistance to a second toxic factor. In order to study the effect of diet on toxin resistance, the Baltimore clinicians placed parallel groups of carefully selected young rats on four qualitative variations of the same basic diet. Each variation contained adequate amounts of all known food factors, including vitamins and salts. The diets differed from one another solely in the relative amounts of protein (casein), carbohydrate (dextrose) and fat (lard). At the end of from two to four weeks on these diets all four groups were tested in parallel for their resistance to toxic agents, the test dose being so selected as to give about 60 per cent mortality in the group of rats maintained on the routine stock diet. In four groups tested by a subcutaneous injection of 0.6 Gm. of phenol per kilogram of body weight, for example, no consistent difference was noted between the mortality rates of the stock group and the groups on high fat or high carbohydrate diets. The group given a superabundance of protein in their daily rations, however, showed a mortality rate only about half of that in the control group. A high protein diet therefore increases phenol resistance. Quite different data were obtained in the four groups tested with 7 mg. of sodium cyanide per kilogram. Here the average mortality was 65 per cent in the three groups on high protein, high carbohydrate and the stock diet. The mortality, however, was only about half that, 33 per cent, in the group on a high fat diet. A superabundance of fat, therefore, causes an increased cyanide resistance. Even more striking differences were noted in the four groups tested with diphtheria toxin. Here the test dose was so selected as to kill two of three control rats in five days. Groups on the stock diet, high carbohydrate diet and high fat diet gave mortality percentages varying from 63 to 68 per cent in their series. In contrast, the high protein group showed a mortality rate of but 16 per cent. Normal antitoxic resistance to diphtheria toxin, therefore, is increased fourfold in effectivity on a high protein diet. No explanation of these quasispecificities have as yet been offered by the Baltimore clinicians.

ORGANIZATION SECTION

MESSAGE OF PRESIDENT ROOSEVELT ON CONSTRUCTION OF HOSPITALS IN NEEDY AREAS AND TEXT OF BILL INTRODUCED BY SENATOR WAGNER

Following is a copy of a message from the President to the Congress of the United States (House Document 604; *Congressional Record*, January 30). Following the receipt of the message, Senator Wagner, on behalf of himself and Senator George, of Georgia, introduced Senate Bill 3230 "to promote the national health and welfare through appropriation of funds for the construction of hospitals," which was referred to the Senate Committee on Education and Labor. Representative Lea, of California, introduced a companion bill in the House of Representatives, H. R. 8240, which was referred to the House Committee on Interstate and Foreign Commerce.

THE PRESIDENT'S MESSAGE

To the Congress of the United States:

In my special message to the Congress on January 23, 1939, I expressed my concern over the inequalities that exist among the states as to health services and resources with which to furnish such services. With that message I transmitted the report and recommendations on national health prepared by the Interdepartmental Committee to Coordinate Health and Welfare Activities and recommended it for careful study by the Congress.

Conditions described a year ago are substantially unchanged today. There is still need for the federal government to participate in strengthening and increasing the health security of the nation. Therefore, I am glad to know that a committee of the Congress has already begun a careful study of health legislation. It is my hope that such study will be continued actively during the present session, looking toward constructive action at the next. I have asked the Interdepartmental Committee to Coordinate Health and Welfare Activities to continue its studies.

In order that at least a beginning may be made I now propose for the consideration of the Congress a program for the construction of small hospitals in needy areas of the country, especially in rural areas, not now provided with them. Hospitals are essential to physicians in giving modern medical service to the people. In many areas present hospital facilities are almost nonexistent. The most elementary health needs are not being met.

The provision of hospitals in the areas to which I refer will greatly improve existing health services, attract competent doctors and raise the standards of medical care in these communities. The new hospitals should serve the additional purpose of providing laboratory and other diagnostic facilities for the use of local physicians, as well as accommodations for local health departments.

The proposed hospitals should be built only where they are most needed; they should not be constructed in communities where public or private institutions are already available to the people in need of service even if these institutions are not up to the highest standards. To insure proper location and good standards of operation, approval of hospital construction projects should be given by the Surgeon General of the Public Health Service, with the advice of an advisory council consisting of outstanding medical and scientific authorities who are expert in matters relating to hospital and other public health services.

Projects proposed for consideration should be submitted by responsible public authorities and should include assurance that adequate maintenance will be provided. Approval of projects should be preceded by careful survey of existing local hospital facilities and needs. Standards for organization, staff and continuing operation should be established by the Surgeon General, with the advice of the advisory council. A competent hospital

staff and satisfactory standards of service should be required, including medical, surgical and maternity service. When indicated, special provisions should be made for the care of the tuberculous. In many areas of the South, the present acute needs for the care of Negro patients should also be met.

I suggest that these hospitals be simple, functional structures, utilizing inexpensive materials and construction methods. The facilities of the Federal Works Agency should be utilized in the planning and execution of the hospital projects. Title to these institutions should be held by the federal government, but operation should be a local financial responsibility.

I recommend to the Congress that enabling legislation for this program be enacted and that a sum of between \$7,500,000 and \$10,000,000 be appropriated to the Public Health Service to inaugurate the program during the next fiscal year.

I am confident that even this limited undertaking will bring substantial returns in the saving of lives, rehabilitation of workers, and increased health and vigor of the people.

This suggestion is not a renewal of a Public Works program through the method of grants in aid. The areas which I have in mind are areas so poor that they cannot raise their share of the cost of building and equipping a hospital. Yet I believe that many of such communities have enough public-spirited citizens with means, and enough citizens able to pay something for hospital treatment, to care for operating costs of a hospital, provided they do not have to pay for its original construction and equipment, or to pay annual interest and amortization on borrowed money. Treatment in such a hospital would, of course, be available to men, women and children who literally can afford to contribute little or nothing toward their treatment.

One of the important difficulties in such areas at the present time is that young doctors hesitate to practice general medicine or surgery because of the utter lack of hospital or laboratory facilities. One cannot blame them.

In such areas also costs of construction are generally low and many local materials can be used. It is my belief that with the assistance of the Work Projects Administration the cost of building and equipping a hundred bed hospital can be kept down to between \$150,000 and \$200,000. This means that we could build fifty such hospitals for between \$7,500,000 and \$10,000,000.

This is not an ambitious project. This principle should not be extended to government gifts to communities which are financially able to build their own hospitals. It is an experiment in the sense that the nation will gain much experience by undertaking such a project.

At the very least it will save lives and improve health in those parts of the nation which need this most and can afford it least.

FRANKLIN D. ROOSEVELT

The White House,
January 30, 1940.

TEXT OF S. 3230, INTRODUCED BY SENATOR WAGNER

Be it enacted by the Senate and House of Representatives of the United States of America in Congress assembled, That this Act may be cited as the "National Hospital Act of 1940."

SEC. 2. For the purpose of assisting states, counties, health or hospital districts, and other political subdivisions of the states in providing better health and medical services through the provision of needed hospital facilities to serve rural communities and economically depressed areas, there is hereby authorized to be appropriated to the Public Health Service for the fiscal year ending June 30, 1941, the sum of \$10,000,000 and for each

fiscal year thereafter such sums as the Congress may deem necessary for carrying out the purposes of this act. Amounts appropriated under this act shall be available until expended.

SEC. 3. States, counties, cities, other political subdivisions or parts thereof alone or in combination wishing to participate in the benefits contemplated by this act shall make application to the Surgeon General of the Public Health Service (hereinafter referred to as the Surgeon General). Said applications shall contain information necessary to establish the existence of need for hospitals, to give assurance acceptable to the Surgeon General that such hospitals will be made available under appropriate conditions to all groups of the population, will be maintained in good repair, and will be utilized in furnishing service of satisfactory quality, in accordance with regulations hereinafter authorized to be prescribed.

SEC. 4. There is hereby established the National Advisory Hospital Council (hereinafter referred to as the "Council") to consist of the Surgeon General as chairman and six members to be appointed by the Surgeon General with the approval of the Federal Security Administrator. The six appointed members shall be selected from leading medical or scientific authorities who are outstanding in matters pertaining to hospitals and other public health services. Each appointed member shall hold office for a term of three years except that (1) any member appointed to fill a vacancy occurring prior to the expiration of the term for which his predecessor was appointed shall be appointed for the remainder of such term, and (2) the terms of office of the members first taking office shall expire, as designated by the Surgeon General at the time of appointment, two at the end of the first year, two at the end of the second year, and two at the end of the third year after the date of the first meeting of the Council. No appointed member shall be eligible to serve continuously for more than three years but shall be eligible for reappointment if he has not served as a member of the Council at any time within twelve months immediately preceding his reappointment. Each appointed member shall receive compensation at the rate of \$25 per day during the time spent in attending meetings of the Council and for the time devoted to official business of the Council under this act, and actual and necessary traveling and subsistence expenses while away from his place of residence upon official business under this act.

SEC. 5. The Council is authorized to advise the Surgeon General with reference to the carrying out of the provisions of this act, including—

(a) The review of applications for hospitals submitted in accordance with and meeting the requirements of section 2 and recommendation of such projects as in its opinion are needed, will be adequately maintained, and otherwise will fulfil the requirements of this act;

(b) The formulation of standards which are necessary to insure proper conduct of the hospitals and care of persons served by the hospitals;

(c) The formulation of rules and regulations necessary to carry out the provisions of this act;

(d) The review of reports and inspections and, when necessary, the making of inspections with reference to professional service and standards of maintenance of the hospitals.

SEC. 6. In carrying out the purposes of this act, the Surgeon General is authorized and directed, after consultation with the Council—

(a) To conduct, assist and foster studies and surveys with respect to needs for hospitalization and problems of hospital operation;

(b) To approve hospital projects, to designate the location, type, equipment and size of hospitals, and to allocate available funds to such approved projects;

(c) To provide training and instruction of personnel who will be required in connection with the hospitals;

(d) To cooperate with state and local health and welfare authorities and with professional agencies;

(e) To secure reports and to make inspections with respect to professional service and standards of maintenance of the hospitals and other matters pertinent to carrying out the purposes of this act;

(f) To adopt such additional means as may be found necessary or appropriate to carry out the provisions of this act, including the safeguarding of the quality of service furnished in hospitals;

(g) To make, with the approval of the Federal Security Administrator, such rules and regulations as may be necessary to carry out the provisions of this act;

(h) To lease hospital projects when completed to the applicant for an indefinite period, the consideration for such lease being the maintenance and operation of said hospital in accordance with the provisions of this act. If at any time said maintenance and operation by the applicant shall fail to meet such provisions, the lease shall be terminated by the Surgeon General on six months' notice.

SEC. 7. When a hospital project has been approved by the Surgeon General, in accordance with the provisions of this act, it shall be certified by the Federal Security Administrator to the Federal Works Agency for construction and there shall be allocated and transferred to the Federal Works Agency, out of funds appropriated pursuant to this act, so much of the appropriation as may be determined to be available for the project, and the Federal Works Agency is authorized to expend such sums for the planning, execution and construction of the project and pertinent facilities, including administrative expenses, site acquisition, the preparation of working drawings and specifications, award of all necessary contracts and supervision of construction; and the Federal Works Agency is further authorized to expend out of appropriations available to it, in accordance with the purposes thereof, such sums as may be necessary for the completion of the project but without regard to specific limitations imposed on the use thereof. Title to the properties so constructed, and to the equipment installed therein, and to the land on which they are located, shall be in the United States.

SEC. 8. The Federal Security Administrator is authorized to accept on behalf of the United States gifts of money, equipment and land to be utilized in carrying out the purposes of this act.

SEC. 9. The President is authorized to allocate from funds appropriated pursuant to this act, for the fiscal year ending June 30, 1941, a sum for all necessary expenses of the Public Health Service in administering the provisions of this act, including the training of personnel; and there is hereby authorized to be appropriated in each succeeding fiscal year such amounts as the Congress may deem necessary for such purpose.

SEC. 10. (a) There is hereby authorized to be appointed in the Public Health Service, in accordance with applicable law, such additional commissioned officers and other personnel as may be necessary in carrying out the provisions of this act.

(b) On recommendation of the Surgeon General, the Federal Security Administrator shall submit to the Bureau of the Budget on or before September 15 of each year a list of approved hospital projects under this act and cost estimates thereof, together with such other data as may be necessary for the preparation of the budget estimates.

(c) This act shall not be construed as superseding or limiting (1) the functions, under any other act, of the Public Health Service or any other agency of the United States relating to the prevention, diagnosis and treatment of disease; or (2) the expenditure of money therefor.

(d) The term "state" as used in this act shall include also the territories and insular possessions of the United States.

(e) The term "hospital" as used in this act shall include the physical facilities necessary for the prevention, diagnosis or treatment of disease, and for the protection of the public health.

(f) The Surgeon General shall include in his annual report for transmission to Congress a full report of the administration of the act, including a detailed statement of receipts and disbursements.

(g) This act shall take effect thirty days after the date of its enactment.

AN ANALYSIS OF S. 3246, A BILL TO AUTHORIZE LOANS FOR HOSPITALS, WATER, SEWER, STREAM-POLLUTION CONTROL, AND RELATED PROJECTS AND FACILITIES

PREPARED BY THE BUREAU OF LEGAL MEDICINE AND LEGISLATION, AMERICAN MEDICAL ASSOCIATION, FEB. 5, 1940

This bill was introduced by Senator Mead, of New York, February 1. It proposes to authorize a federal appropriation of \$300,000,000 to remain available until expended to be utilized in making loans to public bodies and nonprofit organizations to finance the construction, equipment, repair, alteration, extension, improvement and "the temporary operation and maintenance for a period not exceeding four years" of:

(1) hospitals, defined to mean any institutions or facilities for the treatment of illness or disease, including any health, diagnostic or treatment center, station, institution or clinic;

(2) water and sewerage works and systems, including treatment plants and any and all constituent facilities thereof;

(3) works and systems for the reduction of pollution in streams; and

(4) related "facilities" necessary or proper to safeguarding the health of the people, where, in the determination of the Administrator of the Federal Works Agency, such "facilities" are now inadequate or nonexistent. (The bill is silent as to what is to be considered a "related facility.")

Of the sum to be authorized, not to exceed \$100,000,000 may be devoted to hospital projects and not to exceed \$9,000,000 will be made available during the fiscal year ending June 30, 1941, for administrative purposes in carrying out the provisions of the bill.

The bill contemplates that secured loans may be made by the Administrator of the Federal Works Agency to any public body, defined to mean any state, territory, possession or political subdivision, or an instrumentality or agency thereof, and to any organization not operating for profit, and created pursuant to law or under the authority of any public body. Loans will be repayable within a period not to exceed fifty years and will bear interest at the rate of 2 per cent a year.

With particular reference to hospitals, the bill provides that, to the extent not inconsistent with any pertinent state or territorial law, any public body or nonprofit organization receiving

a loan for the construction of a hospital or a hospital addition shall, on the request of the Surgeon General of the Public Health Service, make such hospital or hospital addition available to the federal government for operation by it during (1) a state of war or (2) a "national emergency," the public body or nonprofit organization to be compensated therefor in such an amount as the Congress shall determine to be just and reasonable. The bill does not define what shall constitute a "national emergency" nor does it indicate who is to determine the existence of an emergency so as to justify the Surgeon General of the Public Health Service in taking over the operation of a hospital or addition constructed with money made available by the bill.

The bill provides that it may be cited as the "Health Security Act of 1940." The administration of its provisions, however, is to be devolved solely, with the exception noted in the preceding paragraph, on the Administrator of the Federal Works Agency, who will be authorized to prescribe the terms and conditions on which loans may be made. While it relates to health security, it has been referred to the Senate Committee on Banking and Currency, of which Senator Wagner, of New York, is chairman and who himself on February 1 introduced another bill providing for the construction of hospitals, discussed elsewhere in this issue, which bill was referred to the Senate Committee on Education and Labor.

In submitting S. 3246, its author, Senator Mead, said in part:

"I wish to observe at the outset that my bill will in no wise conflict with a similar bill introduced by my distinguished colleague the senior Senator from New York [Mr. Wagner]. It will supplement the program he proposes, and it will permit applicants who otherwise would not be permitted to apply for funds for this purpose to qualify and, in the end, to build hospital facilities." (*Congressional Record*, Feb. 1, 1940, p. 1361.)

Representative Schulte, of Indiana, has introduced a companion bill in the House of Representatives, H. R. 8288, which was referred to the House Committee on Appropriations.

GRADUATE MEDICAL EDUCATION

A PROGRESS REPORT OF THE FIELD STUDY ON GRADUATE MEDICAL EDUCATION IN THE UNITED STATES BEING CONDUCTED BY THE COUNCIL ON MEDICAL EDUCATION AND HOSPITALS

FLORIDA

Beginning in 1933 the Florida Medical Association has conducted each year a six day graduate short course for physicians. The course consists of six lectures in medicine, surgery, pediatrics and obstetrics and five lectures in gynecology, with the remainder of the time devoted to the clinical specialties. Round table discussions were held in 1934 and 1935. In 1935 there was a symposium on malaria and in 1936 a symposium on respiratory diseases and fractures. Exhibits and demonstrations have been attempted in tuberculosis, radiology, public health and pharmacy.

In 1933 the state medical association appointed a committee on medical postgraduate course. At first there were four and later six members of this standing committee. Representatives were appointed from each of six sections of the state with Dr. T. Z. Cason as chairman since the formation of the committee. The committee men are appointed for a three year period, serving overlapping terms.

The state association has allotted \$500 each year for the expenses of the committee's program. Actually less than \$300 has been spent of the total amount allotted by the state association over the past seven years, so that the per capita cost of instruction has been only slightly in excess of 50 cents. A registration fee of \$5 is charged each year. This is used for paying the traveling expenses of out of state instructors. Since

the committee is incorporated, it is financially independent of the state association. Commercial exhibits have not been attempted.

Instructors are selected by the postgraduate committee usually from the faculties of medical schools. It has been the custom to invite speakers for not more than two consecutive years. On the first year's program local University of Florida instructors participated, but since then only out of state physicians have constituted the faculty. Six or seven men are invited from various sections of the country to speak on subjects of current interest. The first four years' courses were held in Gainesville with the University of Florida General Extension Division cooperating. Notices were prepared by the state association's committee and published and distributed by the extension division, the division being compensated for this service. Attendance has ranged from 102 physicians the first year to 136 in recent years. Of the 2,072 physicians licensed in Florida, 1,346 are members of the state medical association.

In 1937 the university extension division continued to publish and distribute programs for the graduate short course, and the meeting was held in Orlando for the first time. Definite hours were assigned to each instructor, so that the teaching schedule was arranged from 8 a. m. to 5:30 p. m. each day. Attendance increased over previous years. Since 1937 meetings have been held at Daytona Beach.

In 1938 and 1939 the state board of health cooperated with the state medical association, replacing the extension division of the university. The state board of health published and distributed the programs for the postgraduate committee as well as paid instructors, who discussed such subjects as obstetrics, gynecology, pediatrics and venereal diseases.

In 1939 for the first time a short course of one week's intensive work in diseases of the chest was given in connection with the regular graduate short course. Seventeen physicians enrolled, each paying an additional fee of \$5. Hospital facilities at Daytona Beach and Orlando were utilized so that registrants might have an opportunity to study patients under the supervision of a competent teacher.

Over five years approximately half the membership of the state medical association has attended one or more graduate sessions. From a representative group of physicians who were questioned regarding their interest in the graduate short course, it was noted that about two of every five had attended the course given in Florida, about one of six engaged in graduate study elsewhere, and less than one of eight found some reason for not attending the state association's course. The majority favored the present plan and schedule. A number requested additional instruction in such subjects as urology, orthopedic surgery and radiology.

The Florida State Board of Health attempted in January and February 1937 to promote a program of graduate study in six cities in the northern section of the state. Six meetings were held at each locality. These section meetings were sponsored by each local medical society in cooperation with the state association's committees on maternal welfare and child health. One lecture in obstetrics and one in pediatrics were given each day and time was provided for consultations. Twelve out of state instructors were engaged. The same lectures were given on succeeding days throughout each week in each of the six cities. No registration fees were charged. The program was financed with federal funds.

During the past year the committee on medical postgraduate course has taken an active interest in the annual meetings of district societies throughout the state. A member of the state association's committee from each district represents the committee in his own district meeting. It is anticipated that some effort will be made to coordinate the programs of the district meetings with the programs of the annual graduate short course of the state association.

The Florida Tuberculosis and Health Association sponsored a three day course in the Florida State Hospital at Orlando in 1939. While the instruction was designed especially for health officers, others were invited to attend. During the past three years, instruction in tuberculosis for Negro physicians has been sponsored by the state tuberculosis and health association with the financial assistance of the Rosenwald Fund.

NORTH CAROLINA

A feature of the North Carolina plan of graduate education which is most appreciated by physicians of the state is the method of teaching by clinical demonstrations utilizing patients with diseases existing in the physician's own community—their problems of everyday practice. The physician sees modern diagnostic procedures applied at the home and his patient sees them and learns to appreciate and demand careful systematic examination. This tends to raise the standard of medical practice in the community.

Since the problem of postgraduate training is one primarily of education and only secondarily one of public health, in North Carolina it has been considered to be chiefly the concern of the state university rather than the state board of health, and as a result it has been undertaken largely by the university. The organization of classes, the planning of circuits for instructors and other executive work has been carried out by and financed by the university extension division. More strictly medical problems such as the selection of instructors and outline of the course have been in the hands of the medical school administration.

THE UNIVERSITY OF NORTH CAROLINA AND THE NORTH CAROLINA STATE BOARD OF HEALTH

Extension training for practicing physicians of North Carolina originated in Wilson County in 1916. Dr. W. S. Rankin, state health officer and secretary of the board of health, Mr. Chester D. Snell, director of the Extension Division of the University of North Carolina, and Dr. I. H. Manning, dean of the medical school, were concerned with the early development of the plan, which has been described briefly as follows: A lecturer is elected to discuss a subject of interest to physicians practicing in an essentially rural state. Definite days are fixed when the instructor is to appear at previously selected places on the circuit plan. He may spend from twelve to sixteen weeks in the state, appearing the same day each week at the same center. An eastern and a western circuit were developed for the state in 1916, the first year. There were twelve groups of physicians meeting in as many places on the two circuits. Since instruction in pediatrics was most desired, this subject was given by two members of medical faculties from outside the state. After an introductory lecture, from one to ten patients would be brought in for diagnosis, demonstration and discussion by the physicians enrolled in the course. One hundred and seventy-nine physicians registered the first year. The attendance averaged 76 per cent.

After an interruption during the World War period the courses were resumed, and in 1922 twelve localities were supplied by two out of state lecturers in the subject of internal medicine. The initial plan of organization and administration was followed. One hundred and ninety-nine physicians registered, attending 84 per cent of the lectures. Twenty-four groups on four circuits were addressed in 1923. The subjects were internal medicine and pathology. Four out of state physicians participated. Three hundred and eighty enrolled and the attendance continued at 84 per cent. In 1924 and 1925 pediatrics was repeated in twelve localities during each year. Two physicians constituted the traveling faculty in 1924 and three in 1925. The first year 176 physicians registered, the percentage of attendance being 82. In the second year 159 enrolled, with 76 per cent attendance. In 1926 and 1927 instruction in internal medicine was given and pediatrics was repeated in 1927. Three out of state physicians were engaged in 1926 and two in 1927. Attendance was 102 the first year and eighty-six the second year. In 1928 a course in physical diagnosis was given to seven groups of sixty physicians. One out of state instructor was responsible for this course.

During the first eight years eight courses were offered to ninety-one groups of physicians, meeting in forty-four centers located in forty-one counties of the state. Enrollment totaled 905 physicians. There are 2,663 licensed physicians in the state, of which number 1,801 are members of the Medical Society of the State of North Carolina.

Fourteen out of state instructors were engaged over this period. Physicians who enrolled for instruction paid \$30, which was sufficient to finance the traveling expenses and honorariums of instructors for a course of twelve or thirteen sessions. A minimum of fifteen registrants was required under this plan. A member of the Extension Division of the University of North Carolina accompanied the lecturer on his first appearance, introduced him to his audience and took complete charge of the financial arrangements. This procedure has been outlined by Mr. Chester Snell, director of the university extension division, as follows:

In the fall of 1921 I sent a letter outlining our scheme to the secretaries of all the county medical societies in the state, with the request that they bring our proposition up for discussion at their meetings and report back to me. The best responses came from the societies which had taken the work in 1916. In the spring of 1922 I obtained a list of all the doctors within 50 miles of the six selected cities, in the two sections, and sent to each an explanatory letter and an application blank. About forty were enrolled in this way. Next I interviewed personally a large number at the annual convention of the state medical society, which occurred later in the spring, and, following this, I made a personal office-to-office canvass, eventually signing up enough to make the total for the two circuits 180. Just before the first meeting I sent letters to all of the doctors who had been on the former mailing list, reminding them of the dates on which the first meetings were to be held and again soliciting their cooperation. Exactly 198 physicians enrolled, out of a total of about 450 approached. About 85 per cent of the general practitioners could be classified as interested or enthusiastic when first seen. The main difficulty in getting

an early response was due to the fact that when I made my field trip I could not announce the names of the instructors, as they had yet to be selected. Difficulty was occasionally experienced in overcoming, on the part of the more skeptical, a tendency to believe that the university was attempting to "put something over"; but we were usually able to meet this attitude successfully by a thorough explanation of our plan. As further evidence of good faith, we promised a refund to those enrolled in case our receipts more than covered the instructors' expenses. Each physician paid \$30 for the series and later received a refund of over \$3. I believe that, in the future, less difficulty will be experienced in organizing similar classes, for the work is now so firmly established that it should sell itself.

After a lapse of several years the statewide graduate program was revived, which had several of the features of the initial plan. The state board of health administered the program and lent financial aid with federal funds in 1935-1936. An advisory committee was legally constituted to represent the medical profession. This committee was composed of the president and secretary of the Medical Society of the State of North Carolina, the chairmen of the society's committees on maternal and child health, on obstetrics and gynecology and of its section on pediatrics, the chairman of the North Carolina chapter of the American Academy of Pediatrics and of a similar body in obstetrics, the president of the North Carolina Society of Pediatrics, the managing director of the state tuberculosis association and the president and secretary of the state health officers' association.

Beginning in 1935 a series of five illustrated lectures in obstetrics was given in each of the councilor districts of the state medical society. The extension division of the university again administered the course and the dean of the medical school provided instructors. The lectures were held in the fall of 1935 and in the spring and summer of 1936. There were ten sections of the state visited. The first three series were conducted by one instructor from out of the state, the next five by another and the last two by a third physician. Some of the lectures were illustrated with movie films. The sessions began at 2 p. m. and continued for three hours. There was a lecture followed by a showing of film and finally a general discussion. Approximately 600 practicing physicians received some instruction under this plan.

In the fall of 1936 the extension division of the university, the school of medicine and physicians practicing in the state resumed extension training similar to that attempted twenty years before. Under the new system circuits were abandoned in favor of established teaching centers conveniently located for men in general practice. A central committee was formed with the dean of the school of medicine as chairman and with the director of the extension division and Dr. William H. Smith, a member of the postgraduate committee of the state medical society, on this central committee. Before a teaching center is established the plan is approved by the local medical society, which appoints a committee to meet with a representative of the extension division and make local arrangements. An attempt is made to enroll approximately seventy-five physicians at \$15 per registrant. With this amount it is possible to employ six or seven lecturers from out of the state. The meetings begin with supper, which is followed by a lecture of one and one half hours' duration, after which there is a general discussion. Sometimes it is possible to hold late afternoon clinics in local hospitals. It has been found that one lecture a week for six times is most agreeable to physicians, many of whom travel great distances to attend a course. Only five areas of the state have had sufficient numbers of physicians to finance this undertaking. Negro physicians also may attend, coming in after supper and paying a smaller fee.

In 1936 eighty-six physicians enrolled for a course in general medicine and pediatrics. A total of 115 physicians attended one or more lectures. In 1937 115 enrolled and 150 attended a series of seven lectures in general medicine at another center. In 1938 four courses were given in as many centers on subjects of general interest with an enrollment of 371 and an attendance of 495 physicians. In 1939 three courses were given in three centers, 292 enrolling and 468 attending one or more lectures. It was possible for physicians either to enroll for the whole course or to pay a smaller fee and attend only lectures of special interest to them.

It is anticipated that it will be possible to extend this type of educational service to the more sparsely settled localities in the state where there are insufficient numbers of physicians to subscribe for a course. For this purpose it is hoped that a surplus will develop which will be sufficient to meet this need.

DUKE UNIVERSITY MEDICAL SCHOOL

Since 1934 Duke University Medical School has offered physicians of the state one or two symposiums each year on different subjects of medicine. The university provides facilities at the medical school for any doctor who wishes to spend a few days, weeks or months reviewing his knowledge of medicine, surgery, obstetrics, pediatrics or other divisions of clinical or preclinical medicine. Medical graduates from any part of the state may attend clinics and demonstrations in the major divisions of medicine on Saturdays from 9 a. m. to 12:30 p. m., and clinical pathologic conferences, which are held on Wednesday days at 5 p. m.

In 1934 there was a three day fracture course, which was the initial effort of the university in this type of postgraduate training. In the fall of 1935 there was a three day course in gastro-enteric disease in which seventeen out of state physicians discussed diagnosis and treatment. In October 1936 there was a symposium on diseases of the heart, circulation and kidney in which sixteen out of state physicians participated. During this month there was a course on pulmonary diseases which was designed for Negro physicians. This course was given in cooperation with the University of North Carolina and Wake Forest College. In November 1937 there was a three day symposium on pediatrics, gynecology and obstetrics. Ten out of state physicians participated. In addition to the lectures in 1937 there were three round table discussions.

The house of delegates of the Medical Society of the State of North Carolina in May 1938 voted to sponsor intensive short courses for practicing physicians to be given at Duke University School of Medicine. A committee was appointed by the society to publicize these courses. Under this plan the university, as outlined above, permits physicians practicing in the state to spend one or more weeks in residence at the university for observing clinical procedures in the major divisions of medicine.

In January 1938 a one day symposium on pneumonia, which also included a technician course, was given. Eight members of the staff at Duke participated and moving pictures were shown. In October 1938 there was a three day symposium on medical problems at Duke University in which ten out of state and a number of North Carolina physicians participated. In January and February 1939 there was a university extension course in medicine in which there was one lecture each week by an out of state physician. Also in January 1939 the one day symposium on pneumonia was repeated, with two speakers participating. In March 1939 there was a two day graduate clinic for the diagnosis and treatment of syphilis. Seven out of state physicians participated.

WAKE FOREST COLLEGE

In January 1930 there was one day of lectures by an out of state physician on gastro-enteric disease. In December 1931 there was a similar lecture on nerve physiology. In December 1933 there was a two day series of talks on the diagnostic and treatment problems of cancer by four out of state physicians. In April 1938 there was a two day symposium and clinic on tumors in which four out of state physicians participated. Both the 1933 and 1938 discussions were well attended. Approximately 125 physicians enrolled for the 1938 session.

SOUTHERN PEDIATRIC SEMINAR

Each year in Saluda, N. C., is held the Southern Pediatric Seminar. A two weeks course of instruction is given in July or August every year in pediatrics and occasionally obstetrics is included. Lectures, clinics and symposiums are given in a local hospital. Instructors are chosen from medical schools of the South. Attendance in 1938 was forty-seven. There is a registration fee of \$25.

OFFICIAL NOTES

SPECIAL BLUE NETWORK BROADCAST

February 21 from 9 to 9:30 p. m. central standard time (10 to 10:30 eastern standard time, 8 to 8:30 mountain time and 7 to 7:30 Pacific time) there will be a special broadcast by the American Medical Association and the National Broadcasting Company over seventy stations of the Blue network. The subject will be "Pasteur Conquers Rabies."

The broadcast will be based on an article "Watch Your Dog!" appearing simultaneously in *Hygeia* and on official reports dealing with the seriousness of the rabies situation in the United States.

Special features of the program will be music arranged by Don Markotte of the National Broadcasting Company Music Library from the score which accompanied the motion picture production of Louis Pasteur, starring Paul Muni. This music

is made available through the special courtesy of Warner Brothers. An augmented N. B. C. orchestra, directed by Joseph Gallicchio, will render the music. Dramatizations taken from the life of Pasteur and arranged for radio by William J. Murphy will be enacted by a specially selected cast of N. B. C. radio actors, under the direction of J. Clinton Stanley, director of the series *Medicine in the News*.

A limited number of tickets for admission to the studio will be available to physicians in Chicago and vicinity. Tickets will be limited to two per application. Requests should be sent by mail to the Bureau of Health Education, American Medical Association, 535 North Dearborn Street, Chicago, enclosing a stamped, self-addressed envelop. Telephone requests cannot be received. Applications will be filled in the order in which they are received until all the tickets have been distributed.

MEDICAL LEGISLATION

MEDICAL BILLS IN CONGRESS

Bills Introduced.—S. 3230, introduced by Senator Wagner, New York, for himself and Senator George, of Georgia, and H. R. 8240, introduced by Representative Lea, California, propose to authorize for the fiscal year ending June 30, 1941, the sum of \$10,000,000 and for each fiscal year thereafter such sums as the Congress may deem necessary, for the purpose of assisting states, counties, health or hospital districts and other political subdivisions of the states in providing better health and medical services through the provision of needed hospital facilities to serve rural communities and economically depressed areas. S. 3246, introduced by Senator Mead, New York, and H. R. 8288, introduced by Representative Schulte, Indiana, propose to authorize an appropriation of \$300,000,000 from which to make loans to public bodies and nonprofit organizations for hospital, water, sewer, stream-pollution control, and related projects and facilities. H. R. 8235, introduced by Representative Miller, Connecticut, proposes that persons who served during the World War with the American Red Cross, Knights of Columbus or any other auxiliary unit recognized by the Administrator of Veterans' Affairs shall be furnished the same domiciliary care and medical and hospital treatment as furnished by law of veterans' regulations to veterans of the World War suffering from non-service connected disabilities. H. R. 8238, introduced by Representative Summers, Texas, proposes to provide for the incorporation of the United Spanish

War Veterans, which includes in its membership acting assistant surgeons, contract physicians, dentists and veterinary surgeons.

DISTRICT OF COLUMBIA

Bills Introduced.—H. Res. 370, submitted by Representative D'Alesandro, Maryland, proposes to authorize an investigation of the conditions obtaining at the Home for the Aged and Infirm at Blue Plains. S. 3221, introduced by Senator King, Utah, proposes to regulate, in the District of Columbia, the disposal of certain refuse.

STATE MEDICAL LEGISLATION

Kentucky

Bill Passed.—H. 104 passed the House, January 30, proposing to require a physician or other person legally permitted to attend pregnant women to take or cause to be taken a specimen of blood for serologic tests for syphilis from such women as soon as he or she is engaged to attend the woman and has reasonable grounds for suspecting that pregnancy exists.

Mississippi

Bill Introduced.—H. 150 proposes to prohibit the retail sale or distribution of any drug or medicine that contains any quantity of any substance such as barbituric acid, except on the written prescription of a physician, dentist or veterinarian.

WOMAN'S AUXILIARY

Indiana

The board of directors of the auxiliary to the Indiana State Medical Association met in Indianapolis November 2. Plans for the year were presented by Mrs. W. E. Tinney, president, and by the chairmen of standing committees. Dr. Norman M. Beatty, chairman of the Committee on Public Policy and Legislation of the Indiana State Medical Association, discussed public relations and policies of the state association.

The auxiliary to the Vigo County Medical Society met in Terre Haute October 12. Mrs. J. R. Yung, hostess, spoke on Mexico. Forty members were present. The auxiliary gave a benefit bridge party November 6 to raise funds for occupational therapy work for children patients in the Union and St. Anthony's hospitals.

Nebraska

The auxiliary to the Lancaster County Medical Society met in Lincoln October 2 with thirty-five members in attendance. Mrs. Charles C. Tomlinson, Omaha, addressed the group. Mrs. Walter L. Albin addressed the meeting on November 6 on the

subject of her recent world tour. A project of the auxiliary is placing *Hygeia* in every school in the city of Lincoln.

West Virginia

The auxiliary to the Cabell County Medical Society met at Huntington November 9. Thirty-two members were present. Dr. A. E. McClue, Charleston, discussed the Social Security Act, and Dr. Raymond Sloan, Huntington, conditions among the indigent.

The auxiliary to the Kanawha Medical Society met in Charleston November 14, with thirty-eight members in attendance. Dr. R. O. Halloran, Charleston, was speaker, and articles from *Hygeia* were reviewed.

Mrs. V. E. Holcombe, president of the auxiliary to the West Virginia State Medical Association, addressed auxiliaries to the following county societies: Harrison, at Clarksburg, November 2; Logan, at Earling, November 7, and McDowell, at Welch, November 8.

The auxiliary to the Parkersburg Academy of Medicine met November 14, with twenty-five in attendance. Dr. W. A. Beracqua spoke on the subject "Becoming Acquainted with Social Agencies."

Medical News

(PHYSICIANS WILL CONFER A FAVOR BY SENDING FOR THIS DEPARTMENT ITEMS OF NEWS OF MORE OR LESS GENERAL INTEREST: SUCH AS RELATE TO SOCIETY ACTIVITIES, NEW HOSPITALS, EDUCATION AND PUBLIC HEALTH.)

ARKANSAS

Arkansas Basic Science Act Constitutional.—The Supreme Court of Arkansas, January 15, in the case of *Stroud v. Crow*, upheld the constitutionality of the basic science act enacted by the legislature of that state in 1929. The case was prosecuted by the members of the executive board of the Arkansas Medical Society, suing in their official capacities and individually as licensed physicians, to enjoin the chiropractic board from issuing chiropractic licenses to persons not possessing basic science certificates, which it had been doing, and to enjoin certain chiropractors from continuing the practice of chiropractic under the purported authority of licenses issued to them by the chiropractic board contrary to the requirements of the basic science act. To the contention of the chiropractors that they did not treat disease and hence were not amenable to the requirements of the basic science act, the Supreme Court answered "If he [the chiropractor] does not treat diseases, what does he treat? Does he manipulate the vertebrae of a well person just for the pleasure of such well person? There would be no excuse for any regulatory chiropractic laws, if they were not engaged in treating disease." The court further held that the basic science act was not invalid because it required chiropractors to be proficient in bacteriology and pathology, two subjects not included in the chiropractic act, or because it exempted from its requirements dentists, nurses, midwives and certain others. The trial court had dismissed the complaint but the Supreme Court said that if chiropractors want to obtain licenses in Arkansas they must first comply with the basic science act. Peter A. Deisch, Esq., of Helena, was attorney for the medical society.

CALIFORNIA

Personal.—Dr. William A. Swim, Los Angeles, has been appointed a member of the state board of medical examiners, succeeding Dr. John MacLean, whose term expired. —Dr. Anthony J. J. Rourke, assistant director, University Hospital, Ann Arbor, Mich., has been appointed medical superintendent of the Stanford University Hospitals, San Francisco, and assistant professor in the university school of medicine.

DISTRICT OF COLUMBIA

Regional Meeting on Pediatrics.—The annual meeting of region 1 of the American Academy of Pediatrics will be held April 4-6 at the Mayflower Hotel, Washington, with District members of the academy acting as hosts.

Joint Meeting of Gynecologists.—Four honorary fellowships were announced by the Washington Gynecological Society at its joint meeting in Washington with the Obstetrical Society of Philadelphia, January 18. The fellowships were conferred on Drs. Jennings C. Litzenberg, professor of obstetrics and gynecology, University of Minnesota Medical School, Minneapolis; Dr. Nicholson J. Eastman, professor of obstetrics, Johns Hopkins University School of Medicine, Baltimore; Marvin Pierce Rucker, Richmond, Va., and Norris W. Vaux, professor of obstetrics, Jefferson Medical College, Philadelphia. The morning program consisted of four round table discussions on the following subjects: obstetric analgesia and anesthesia; induction of labor, indications and methods; hysterectomy—total versus subtotal, and sterility, diagnosis and treatment. The speakers in the afternoon program included Carl Voegtlin, Ph.D., of the National Cancer Institute, who gave the address of welcome, and the following:

Dr. Harold L. Stewart, Bethesda, Md., Pathologic Anatomy of Mammary Tumors of Mice.

Harold B. Andervont, Sc.D., senior biologist, U. S. Public Health Service, Influence of Inbreeding and Foster Nursing on Spontaneous Mammary Tumors in Mice.

Harold P. Morris, Ph.D., Relation of Some Essential Amino Acids to the Growth of Mammary Tumors.

Dr. Michael B. Shimkin, Bethesda, Md., "Carcinogenicity" of Estrone and Stilbestrol.

The program included clinics at the Garfield Memorial Hospital, Gallinger Municipal Hospital and the health department clinic. The speakers at the dinner included Drs. Thomas B.

Lee, Camden, N. J., president of the Obstetrical Society of Philadelphia, George M. Laws, Clifford B. Lull, Norris W. Vaux, Francis Sidney Dunne, Philadelphia; James H. Underwood, Woodbury, N. J., and Fred B. Nugent, Reading, Pa.

GEORGIA

Personal.—Dr. Jack R. McMichael, Quitman, has been appointed a member of the state board of health, succeeding Dr. Cyrus K. Sharp, Arlington. —Dr. George M. Anderson, Eastman, is reported to have resigned as health officer of Dodge County, effective December 31.

The L. C. Fischer Awards.—Drs. William Howard Hailey and Hugh E. Hailey, Atlanta, have received the annual Dr. L. C. Fischer Awards, presented through the Fulton County Medical Society, for their paper on "Familial Benign Chronic Pemphigus." The award of \$100 was given for the paper showing the best research. For the best written paper, Dr. David Henry Poer won the award for his paper entitled "Clinical Experience with Use of Dihydrotychosterol (A. T. 10) in the Treatment of Ten Cases of Hypoparathyroidism—A Comparison with Parathyroid Hormone and Vitamin D."

ILLINOIS

Fellowships in Medicine and Dentistry.—The Graduate School of the University of Illinois has established four research fellowships to be awarded for one year in the fields of medicine and dentistry in Chicago at a stipend of \$1,200 a year (calendar year with one month's vacation). Fellows are eligible for reappointment in competition with new applicants. Candidates for these fellowships must have completed a training of not less than eight years beyond high school graduation. The training may have been acquired in any one of the following ways or the equivalent thereof:

1. Work leading to the B.S. and M.D. degrees (in some instances the candidates would have the M.S. degree or an additional year or two of hospital training beyond the intern year).
2. Work leading to the B.S., M.S. and D.D.S. degrees.
3. Work leading to the B.S. or B.A. degree in a four year collegiate course and to the D.D.S. degree.
4. Work leading to the B.S., D.D.S., and M.D. degrees.

Candidates should indicate the field of research in which they are interested and submit complete transcripts of their scholastic credits, together with the names of three former science teachers as references. March 1 is the deadline for acceptance of applications. Announcement of the fellowship awards will be made on April 1, becoming effective on September 1. Formal application blanks may be secured from the secretary of the committee on graduate work in medicine and dentistry, 1853 West Polk Street, Chicago.

Chicago

Public Lecture by Dr. Musser.—A public lecture, sponsored by the Chicago Medical Society and the Chicago Heart Association, was delivered on February 7 by Dr. John H. Musser, professor of medicine, Tulane University of Louisiana School of Medicine, New Orleans, on "The Growing Importance of Coronary Disease."

Joint Meeting on Urology.—A joint meeting of the Chicago, Cleveland and Detroit Urological societies was held at the Palmer House January 25. Dr. Charles Morgan McKenna addressed the meeting on "Problems in the Diagnosis of Renal Tumors" and Drs. Harry W. Plaggemeyer, Detroit, and William E. Lower, Cleveland, gave the discussions. Dr. Vincent J. O'Connor spoke on "The Treatment of Renal Tumors" and Drs. Reed M. Nesbit, Ann Arbor, Mich., and James J. Jockson, Cleveland, were the discussants. A clinical meeting was held in the morning at the Billings Hospital.

Dr. Hamilton Anderson Goes to China.—Dr. Hamilton Anderson, of the staff of the Council on Medical Education and Hospitals of the American Medical Association, has resigned, effective February 15, to accept a professorship in pharmacology at Peiping Union Medical College, Peiping, China. Dr. Anderson graduated at the University of California Medical School in 1930 and joined the division of pharmacology the same year. He served as assistant clinical professor from 1934 until 1937, when he joined the staff of the American Medical Association. He engaged in field studies on amebiasis for the university at the Gorgas Memorial Laboratory, Panama, in 1931, and on leprosy at the Instituto Oswaldo Cruz, Rio de Janeiro, Brazil, in 1934. Dr. Anderson plans to sail from San Francisco for Peiping, March 22.

Society News.—Dr. Henry P. Wagener, Rochester, Minn., addressed the Chicago Ophthalmological Society January 15 on "Clinical Significance of Retinal and Choroidal Arteries."

sclerosis."—A symposium on the cement industry was presented before the Chicago Tuberculosis Society January 18 by Mr. A. J. R. Curtis, assistant general manager, Portland Cement Association; Drs. Clarence O. Sappington and Milton H. Kronenberg, all of Chicago.—The Chicago Neurological Society was addressed January 18, among others, by Drs. Alexander R. MacLean, Rochester, Minn., on "Relationship of Orthostatic Hypotension to Myasthenia Gravis" and Norman Reider, Topeka, Kan., "Aphasia Due to Exsanguination."—Dr. George L. Streeter, Carnegie Institution of Washington, Baltimore, discussed "Episodes in the Doctrine of the Three Germ Layers" before the Chicago Gynecological Society January 19.—At a meeting of the Chicago Society of Industrial Medicine and Surgery January 23 the speakers were Drs. James K. Stack on "Structural Hand Injuries and Their Repair: Bone Injuries of the Wrist and Hand"; Michael L. Mason, "Repair of Tendon Injuries of the Hand," and Paul W. Greeley, "Plastic Repair of Cutaneous Injuries to the Hand."—Dr. Ernest E. Irons was chosen president of the Society of Medical History of Chicago, January 31; other officers are Drs. George H. Coleman, secretary-treasurer; Morris Fishbein, editor of the *Bulletin*, and the following councilors: Ludvig Hektoen, James B. Herrick, William A. Pusey, David J. Davis, James P. Simonds and Arthur F. Abt.

KENTUCKY

Physicians Honored.—Drs. Daniel M. Griffith and John C. Hoover, Owensboro, and John M. Clayton, West Louisville, were guests of honor at a dinner given by the Daviess County Medical Society in Owensboro in December, in tribute to their long years of service. All have practiced more than fifty years. Dr. Robert Haynes Barr, Owensboro, was master of ceremonies and the speakers were Drs. Granville S. Hanes, Louis Frank and Virgil E. Simpson, all of Louisville, and Leslie C. Dodson, William L. Tyler Sr. and Otway W. Rash, all of Owensboro.—M. H. Dailey, D.D.S., and Dr. John A. Gilkey, Paris, were honored at a banquet given by the Bourbon County Medical Society, Paris, January 18, in recognition of their many years of service to the community.

Society News.—Dr. Henry C. Sweany, Chicago, addressed the Jefferson County Medical Society, Louisville, recently on "Some Important Complications of Tuberculosis." Dr. Bayard T. Horton, Rochester, Minn., was the guest speaker December 18 on "Use of Histamine and Histaminase in Clinical Medicine."—Dr. Hans Brunner, Chicago, addressed the Louisville Eye and Ear Society January 11 on "Pathologic Changes in the Middle Ear After Radical Mastoid Operation."—Drs. Charles D. Caywood and Richard G. Elliott II, Lexington, addressed the Bourbon County Medical Society, Paris, in December on "Present Day Knowledge of Poliomyelitis" and "Diagnosis and Treatment of Poliomyelitis" respectively.—Dr. Samuel A. Overstreet, Louisville, addressed the Whitley County Medical Society, Corbin, January 8, on treatment of ulcer of the stomach.

MAINE

Society News.—Dr. Grantley W. Taylor, Boston, recently discussed "Management of Carcinoma of the Breast" before the Cumberland County Medical Association.—At a meeting of the Kennebec County Medical Association in Augusta, December 21, Dr. John H. Talbott, Boston, spoke on "Water and Salt Metabolism."

MARYLAND

Dr. Perrin Long Named to New Department.—Dr. Perrin H. Long, associate professor of medicine, Johns Hopkins University School of Medicine, Baltimore, has been appointed head of a new department of preventive medicine at the school. The department was established through a grant from the Rockefeller Foundation, allowing \$350,000 during the next ten years, according to *Science*. A graduate of the University of Michigan Medical School, Ann Arbor, 1924, Dr. Long served as assistant and associate with the Rockefeller Institute for Medical Research, New York, from 1927 to 1929, when he went to Johns Hopkins.

MICHIGAN

The Beaumont Lectures.—Dr. Alfred Blalock, professor of surgery, Vanderbilt University School of Medicine, Nashville, Tenn., delivered the annual Beaumont lectures of the Wayne County Medical Society, Detroit, February 5-6. His subject was "Surgical Therapeutics: A Consideration of Shock and Other Problems."

Graham Davis Heads Hospital Program.—Graham L. Davis, who has been associated with the Duke Endowment in Charlotte, N. C., since 1924, has been appointed director of the rural hospital program of the W. K. Kellogg Foundation, Battle Creek, according to *Modern Hospital*. Mr. Davis, assistant to Dr. Watson S. Rankin, Charlotte, N. C., trustee of the Duke Endowment and director of its hospital and orphans' section, is a member of the council on administrative practice of the American Hospital Association and chairman of the committee on accounting and statistics.

Michigan Basic Science Act Constitutional.—According to the January 24 issue of the *Detroit Legal News*, the Circuit Court of Wayne County has upheld the constitutionality of the Michigan basic science act, passed in 1937, in the case of *George Timpona and Marie Hyland Timpona, his wife, v. Brown et al.* The court said that it cannot be denied that the purpose and effect of the basic science act are salutary and that it represents another step forward in the movement which has received frequent legislative endorsement in recent years to protect the public health by requiring those who undertake to cure human ailments to be well qualified in their various professions. The purpose of the act, the court said, is certainly in conformity with high public policy when it insists that practitioners be well grounded in those rudimentary scientific subjects which underlie the healing art. The court dismissed as being without validity a contention made by the plaintiffs that the basic science act was unconstitutional because of the fact that it exempted dentists from its requirements.

MINNESOTA

J. G. Halland Sentenced Again.—John G. Halland, who was formerly licensed to practice medicine in Minnesota, was sentenced at Slayton to a term of fifty days in the Cottonwood county jail recently. Judge J. K. Campbell found Halland "guilty of interfering with the rural schools of Murray County by frightening the teachers and inspecting school records without proper authority from the county superintendent or the commissioner of education." Halland graduated at the University of Minnesota Medical School in 1919 with the degree of bachelor of medicine. His license was revoked by the state board in 1931 because of habitual indulgence in the use of drugs. In 1925 he served one year in jail at Santa Fe, N. M., for a violation of the federal narcotic law, according to the state board. In 1928 he served fourteen months in the federal penitentiary at Leavenworth, Kan., for a similar offense committed at Denver. In 1932 he served seventy days in the Minneapolis Workhouse. In September 1933 he pleaded guilty in the district court at Fergus Falls to an information charging him with practicing medicine without a license. At that time he was given a suspended sentence of six months.

NEW YORK

Society News.—Dr. James Ewing, New York, addressed the Medical Society of the County of Westchester, White Plains, January 16, on "Advantages of Local Control of Cancer Service." The society cooperated with the cancer clinics of hospitals in the county and with the official and voluntary agencies interested in cancer in presenting an exhibit on cancer, January 13-17. Drs. Lewis Gregory Cole and his son, Dr. William Gregory Cole, received the first James Ewing Award, a scroll presented by the county society for a meritorious exhibit contributing to understanding and control of malignant diseases.—Drs. George Porter Robb and Israel Steinberg, New York, addressed the Nassau County Medical Society, Garden City, January 30, on "Visualization of the Chambers of the Heart and of the Thoracic Blood Vessels," discussing disease of the heart and of the lungs, respectively.

New York City

Fifth Harvey Lecture.—Homer W. Smith, Sc.D., professor of physiology, New York University College of Medicine, will deliver the fifth Harvey Lecture of the current series at the New York Academy of Medicine, February 15, on "Physiology of the Renal Circulation."

Alumni Program.—The Alumni Association of New York University College of Medicine will hold its annual Alumni Day program on February 22. The general subject will be "Modern Aspects of Preventive Medicine." In the morning, papers will be presented by Drs. Harry S. Mustard, Frank A. Calderone, Evan W. Thomas, Mortimer D. Speiser and Robert S. Hotchkiss. Speakers on the afternoon program will be Drs. Leonard J. Goldwater, Thomas Francis Jr., Elaine P. Ralli and Norman H. Jolliffe. At a noon luncheon there will be addresses by Drs. John L. Rice, health commissioner of

New York; Samuel A. Brown, dean emeritus of the medical school; Currier McEwen, dean, and the chancellor of the university, Harry Woodburn Chase, Ph.D. Dr. James W. Smith is president of the association.

New Medical College Building Dedicated.—The New York Medical College, Flower and Fifth Avenue Hospitals recently dedicated a new \$1,500,000 building for the college. Harold Willis Dodds, Ph.D., president of Princeton University, Princeton, N. J., made the dedicatory address and other speakers were Mr. Charles D. Halsey, chairman of the board of trustees; Mayor La Guardia, and Dr. Lewis Hill Weed, Baltimore. The new building is nine stories high and is connected floor by floor with the Flower and Fifth Avenue Hospitals. On the first floor are the administrative offices and an auditorium that will seat about 400 persons. The library and other student facilities are on the second and arrangement of the other floors is as follows: third, chemistry and physiology laboratories, with the necessary offices and conference rooms; fourth, department of medicine; fifth, histology and embryology and bacteriology laboratories; sixth, clinical pathology; seventh, department of anatomy; eighth, pathology, and ninth, department of surgery. An attempt has been made to locate the laboratories in the college building in close proximity to the sources of their work in the hospital; for example, the

New home of New York Medical College.

pathology laboratory is on the same floor as the operating rooms. The building also includes a new outpatient department with an entrance on One Hundred and Fifth Street; the college building opens on One Hundred and Sixth Street.

NORTH CAROLINA

Changes in Health Officers.—Dr. Frank E. Wilson, Williamston, has been appointed health officer of Edgecombe County, succeeding Dr. Lorenzo L. Parks, who resigned to join the state health department of Florida, it is reported. Dr. John W. Williams, formerly of Monroe, La., has succeeded Dr. Wilson in Martin County. Dr. Ralph J. Sykes, Weldon, recently health officer of Halifax County, has resigned to join the staff of the state health department.

OHIO

Society News.—Dr. Jacob R. Buchbinder, Chicago, addressed the Montgomery County Medical Society, Dayton, January 19, on "Recognition and Treatment of Acute Suppurative Pericarditis." Dr. Norris J. Heckel, Chicago, addressed the Academy of Medicine of Toledo and Lucas County, January 12, on "Diagnosis and Treatment of Sterility in the Male." Dr. James B. Herrick, Chicago, addressed the Cleveland Medical Library Association at its annual meeting, January 19, on "Jean-Baptiste Bouillaud and His Contributions to Heart Disease."

Physicians Honored.—Six members of the Fairfield County Medical Society who have practiced more than forty years were honored at a dinner given by the society in Lancaster, January 4. The guests were Drs. George P. Huddle, Stoughton; Adelbert V. Lerch, Pleasantville; Charles M. Alt, Baltimore, and George O. Beery, Charles A. Barrow and George W. Beery, Lancaster. Dr. Frank H. Stuke, Lancaster, president of the society, presided. A plaque was presented to each

honored guest.—Drs. William K. Ruble and Austin C. Roberts, Wilmington, were guests of honor at a dinner given by the Clinton County Medical Society in Wilmington, January 16, in recognition of their long careers in medicine. Dr. Ruble, who recently retired after seventeen years as health officer of Clinton County, entered practice in 1890 after graduating from Eclectic Medical College, Cincinnati, and Dr. Roberts began practice in 1890 after his graduation from Starling Medical College, Columbus. Dr. Leland H. Fullerton, New Vienna, president of the society, was toastmaster at the dinner.

OKLAHOMA

Society News.—Drs. W. J. Trainor and Fred E. Woodson, Tulsa, addressed the Garfield County Medical Society, January 25, on "Causes of Cardiac Failure" and "Selection of an Anesthetic for the Cardiac Patient" respectively.—Dr. John L. Emmett, Rochester, Minn., addressed the Pottawatomie County Medical Society, Shawnee, January 15, on "Excerpts from Medical History."

Course in Pediatrics.—A two year postgraduate program of lectures in pediatrics will begin on February 12 with a circuit of towns in northeastern Oklahoma. Drs. Hugh McCulloch and Wayne A. Rupe, St. Louis, will be the first lecturers. The Commonwealth Fund and the state health department are cooperating in financing the course, which has been arranged by the committee on postgraduate education of the state medical association.

OREGON

Postgraduate Course on Heart Disease.—The department of medicine of the University of Oregon Medical School, Portland, announces a postgraduate course on heart disease, February 26-28. Thirty-three lectures are listed in the program, which will be presented in morning and afternoon sessions and evenings of the first two days. The fee will be \$15.

The Jones Lectures.—Dr. Herbert M. Evans, professor of anatomy and Morris Herzstein professor of biology, University of California Medical School, Berkeley, gave the annual N. W. Jones Lectures at the University of Oregon Medical School, Portland, January 18-19. His subjects were "New Light on the Biological Role of Vitamin E" and "Some Unsolved Problems in Anterior Pituitary Physiology."

Society News.—Dr. Harold K. Faber, San Francisco, addressed the Portland Academy of Medicine January 25-26 on "Active Immunization in Pertussis and Tetanus" and "Some Problems in Poliomyelitis." Dr. Faber was also the guest of the North Pacific Pediatric Society January 27, conducting a clinic at Doernbecher Hospital and leading a round table discussion on active immunization of tetanus and whooping cough. Dr. Edwin E. Osgood, Portland, also addressed the pediatric meeting on "Some Recent Observations on Chemotherapy Using Bone Marrow Culture" and Dr. Joseph B. Bilderback, Portland, was a special guest as president of the American Academy of Pediatrics.—Dr. Leo S. Lucas, Portland, addressed the Multnomah County Medical Society, Portland, January 3 on "Physiotherapy in Orthopedic Surgery."—Drs. Lionel D. Prince, San Francisco, and Leo L. Stanley, San Rafael, Calif., addressed the Central Willamette Medical Society, Eugene, recently on "Fractures of the Patella" and Medical Problems of the State Penitentiary" respectively.—Dr. Frank W. Lynch, San Francisco, gave three lectures before the Polk-Yamhill-Marion Counties Medical Society in Salem December 11 on "Cancer of the Uterus," "Prolapse of the Uterus" and "Uterine Bleeding."

PENNSYLVANIA

Epidemic Meningitis.—Twenty-five persons have been stricken with spinal meningitis in Wilkes-Barre since January 1 and thirteen have died, newspapers reported, January 30.

Philadelphia

Dinner in Honor of Dr. Pfahler.—The Philadelphia Roentgen Ray Society sponsored a dinner in honor of Dr. George E. Pfahler, professor of radiology, University of Pennsylvania Graduate School of Medicine, January 25, at the Warwick Hotel. Dr. Eugene P. Pendergrass was toastmaster and the speakers were Drs. Joseph E. Roberts Jr., Camden, N. J., president of the society; Francis F. Borzell, president-elect of the Medical Society of the State of Pennsylvania; George H. Mecker, LL.D., dean of the graduate school of medicine, and Dr. Joseph McFarland, emeritus professor of pathology, University of Pennsylvania School of Medicine. The program

was a large fol- gnatures of several hun-
dred physicians, from many parts of the
country, and a ahler.

Site for Convalescent Hospital.—Fulfilling the terms of a bequest made in 1923, a site has been purchased for the erection of the Magee Memorial Hospital for Convalescents. Mrs. Anna J. Magee, who died on Dec. 12, 1923, left \$600,000 to found and endow an institution "whose object shall be the relief of the general hospitals of the city of Philadelphia from the burden of the support of patients who have passed through the active stages of acute illness." The terms of the will stipulated that the hospital should be controlled by a board of trustees representing eleven Philadelphia hospitals and the physician of the new convalescent hospital. The latter is to be the incumbent professor of medicine at Jefferson Medical College. Children under 14 years of age and persons suffering from incurable or contagious disease will not be admitted. The principal fund left by Mrs. Magee has been allowed to accumulate during the years since her death. The site of the new hospital, which will have between seventy-five and 100 beds, is an elevation overlooking Fairmount Park.

PHILIPPINE ISLANDS

Society News.—At the October meeting of the Manila Medical Society the speakers were Drs. Paterno S. Chikiamco and Clodualdo T. Orquiza on "Roentgen Diagnosis of Ascariasis in the Gastrointestinal Tract"; Geminiano de Ocampo, "The Role of Ophthalmology and Otolaryngology in Some Problems of Internal Medicine"; Gervasio Santos Cuyugan, Fortunato S. Guerrero and Pedro T. Nery, "Tuberculosis of the Cecum."—Dr. Fernando G. Medina, among others, addressed the Cavite Medical Society in October on "Frequency of Errors in the Differential Diagnosis Between Pneumonia and Bronchial Asthma and Gastrointestinal Diseases."—Dr. Eugenio Alonso, Cebu, addressed the Cebu Medical Society in October on "Blood Typing in Establishing Paternity."

PUERTO RICO

Sanitation Facilities in Rural Areas.—The Department of Health of Puerto Rico is building sanitary facilities in the rural areas of the island as a part of the anti-hookworm campaign with a fund of \$450,000 allotted by WPA and \$130,000 appropriated by the insular government. It is planned that 25,000 units will be built by June 30, when the work must be completed.

Study of Diarrhea and Enteritis.—The U. S. Public Health Service, in cooperation with the Puerto Rico Department of Health, is extending to the island a study of diarrhea and enteritis that has been carried on in certain areas of the United States. Dr. Albert V. Hardy will direct the study and Dr. James L. Watt of the public health service will assist in carrying out the project at the biologic laboratory in San Juan.

GENERAL

Base Hospital Reunion Planned.—All officers, enlisted men and nurses who were connected with the U. S. Army Base Hospital at Camp Sevier, S. C., during the war period 1917-1919 are asked to communicate with Mr. Mahlon R. Callaway, 566 West Third Street, Dayton, Ohio, concerning plans for a proposed reunion. Mr. Callaway, a former enlisted man, is the organizer of the U. S. Army Base Hospital Camp Sevier Reunion Association.

Society News.—Dr. John Cotten Tayloe, Washington, N. C., was elected president of the Seaboard Medical Association of Virginia and North Carolina at its annual meeting at Virginia Beach, Va., December 12-14. Dr. Clarence Porter Jones, Newport News, Va., was reelected secretary. Among the speakers were Drs. Raymond A. Vonderlehr, U. S. Public Health Service, Washington, D. C., on the program for control of syphilis and Edwin P. Lehman, Charlottesville, Va., on diagnosis of cancer of the breast.

Examination by Board of Obstetrics.—The general oral and pathologic examinations (part II) of the American Board of Obstetrics and Gynecology for all candidates (groups A and B) will be conducted by the entire board at the Atlantic City Hospital, Atlantic City, N. J., from Friday June 7 through Monday June 10, prior to the meeting of the American Medical Association. Candidates are requested to notice that the dates of the examinations have been advanced one day from those previously announced. Application for admission to group A, part II examinations must be filed with the secretary not later than March 15. Candidates for reexamination in part II must make written application before April 15. The

board's annual dinner will be held at the Hotel McAlpin, New York, June 12. For further information and application blanks, address Dr. Paul Titus, Secretary, 1015 Highland Building, Pittsburgh.

Campaign to Extend Birth Control.—At the annual meeting of the Birth Control Federation of America in New York, January 24, plans were made for a campaign to extend and develop the movement for birth control. Dr. Woodbridge E. Morris, New York, general director of the federation, is chairman of the newly formed National Committee for Planned Parenthood, which will conduct a campaign for \$289,117 to finance the federation for the fiscal year 1940-1941. The committee is divided into groups representing education, religion, public health and medicine, social welfare, science, literature, business, law and philanthropy and women in civic affairs. The group representing public health and medicine are Dr. Carl V. Reynolds, Raleigh, health officer of North Carolina, said to be the first state to include birth control in its public health program; Charles-Edward A. Winslow, Dr. P.H., New Haven, Conn., and Miss Annie W. Goodrich, dean emeritus of the Yale University School of Nursing. Dr. Hans Zinsser, Boston, with Earnest A. Hooton, Ph.D., professor of anthropology at Harvard University, Boston, represent science.

Beware of Fraudulent Salesmen.—The California State Board of Medical Examiners recently reported the activities of one Logan Matthew Franey, who is said to be posing as a salesman for the medical book store of J. W. Stacey, Inc., San Francisco, after having been discharged by that firm. Franey was employed in October 1939 and sent to Seattle. The Stacey firm was informed by the librarian of the King County Medical Society, Seattle, that Franey had sold as his own certain books belonging to the company. It appeared that he had converted to his own use about \$150 worth of books. Cash advances amounting to \$125 had also been made to him and he had a gasoline credit card with which he had run up an account of \$142.04. Gasoline receipts show that he had been in Washington, Montana, Idaho and Oregon during October and November. As Franey retained a list of prospects furnished by the Stacey firm, physicians are warned to watch for him.—The American Surgical Trade Association reports again that swindlers are calling on physicians and hospitals claiming to represent surgical dealers. These swindlers obtain surgical instruments under the pretense that they will be repaired or replated. The instruments are not returned. Recently a man made a practice of calling on hospitals, claiming to be employed by a manufacturer of compressors and pumps and offering to repair the apparatus belonging to the hospital at reasonably low prices. The association urges physicians and hospitals not to turn over surgical instruments to strangers without absolute proof of their identity and authority.

CANADA

Gross Memorial Lecture.—Dr. Maude E. S. Abbott, Montreal, gave the second annual Louis Gross Memorial Lecture at the Jewish General Hospital, Montreal, recently. Dr. Abbott's subject was "The History of Medicine in the Province of Quebec."

Society News.—Dr. James Herbert Mitchell, Chicago, addressed the Academy of Medicine of Toronto December 5 on "Differential Diagnosis and Treatment of Cutaneous Lesions of the Hands and Feet." Dr. Paul M. Wood, New York, was the guest speaker at a meeting of the section of anesthesia January 29 on "Preoperative and Operative Care of the Handicapped Patient Suffering from Anoxemia."

Cancer Clinic in Saskatchewan.—The Saskatchewan Cancer Commission, the provincial department of health and the Regina Grey Nuns Hospital have recently cooperated in the construction of a special building for diagnosis and treatment of cancer, said to be the first in Canada designed especially for this purpose. The building is a four story wing on the Grey Nuns Hospital erected at a cost of \$150,000. Offices, examination and treatment rooms and a surgery are on the second floor; the third and fourth have twenty beds each. The Saskatchewan Cancer Commission was formed in 1930 by the department of health and shortly opened clinics in Regina and Saskatoon, with about 2.5 Gm. of radium. The volume of work grew until two full time physicians were appointed for the Regina Clinic in 1939 and it was moved from the Regina General Hospital to the Regina Grey Nuns Hospital. Other agencies interested have been the cancer committee of the Saskatchewan College of Physicians and Surgeons and the Saskatchewan Branch of the Canadian Society for the Control of Cancer.

Foreign Letters

LONDON

(From Our Regular Correspondent)

Jan. 10, 1940.

Transportation by Air of Blood for Transfusion

In previous letters the arrangements for a blood transfusion service in the war on a scale never known before were described. As stated, transportation by air plays an important part and further details are now available. There is a fleet of aircraft to carry blood from the depots in which it is stored to the hospitals. A wire crate containing ten bottles of blood is the unit for dispatch. To each bottle is attached a tin box containing the sterilized equipment necessary for giving the blood. There are insulated boxes for the airplanes, each of which holds two crates and when loaded weighs about 100 pounds. The boxes are kept loaded in the refrigerator until just before dispatch. Thereupon a block of ice contained in a tin box is slipped into the lid of the box. This, in conjunction with the kapok insulating material with which the walls of the box are lined, ensures that the temperature inside the box will not rise more than 5 degrees C. in eight hours. Little structural change is required in the aircraft used for the work. The boxes are merely strapped to the fuselage to prevent rolling when in flight. The type of aircraft used can carry five boxes of blood; that is, 100 pints.

Treatment of War Fractures by the Closed Method

At the Royal Society of Medicine Dr. J. Trueta, late director of surgery at the General Hospital of Catalunya, Barcelona, described his method of treating war fractures, which gave good results in the Spanish civil war. Advance in the treatment of compound fractures had always been secured by the experience of war. He particularly discussed injuries from aerial bombs, which were more destructive than those from bullets. No measures against infection, such as antiseptics or serum, were used today without first excising damaged tissue. Contrary to the opinion held during the great war by surgeons, such as Leriche, he believed that the greatest danger of infection lay not in bone but in muscle, which was favorable soil for anaerobic infection. In extensive wounds of the limbs, Trueta observed clinically, perhaps for the first time on a large scale, that true shock is the result of absorption of disintegrating tissues. After air raids on Barcelona he operated radically on hundreds of persons with severe wounds of the limbs within half an hour and sometimes within twenty minutes. After treatment of the primary shock a meticulous operation was performed, all devitalized tissue being removed. When operation was undertaken immediately it was common to observe that secondary shock or generalized infections did not occur.

Movement increased the dissemination of infection in the body and rigorous immobilization prevented it. This could be obtained only by enclosing the limb in a rigid casing which prevented all movement and permitted good circulation. The only material which supplied this requisite was plaster of paris. Its only disadvantage was that it prevented examination of the wound, but this was seldom necessary. In the upper limb, if properly applied, the closed method was always satisfactory and gas gangrene and septicemia were very rare. In the lower limb the leg and the thigh must be separately considered. In fractures of the leg the circulation of the foot and the local circulation in the wounded part and the possibility of excising devitalized tissue must be carefully estimated. If, in spite of excision, there was still doubt about the vitality or the circulation, one should wait a day or two before putting on plaster, using open treatment with continuous traction. If amputation became necessary, it could then be performed without loss of

time. In the thigh the indications were the same, but the local circulation of the tissues surrounding the wound was more important than the general circulation of the leg, which was easier to assess. By this treatment many lives as well as limbs could be saved and gas gangrene disappeared from the hospital.

Reduction of fractures must be secured by traction on the operating table. The plaster of paris should then be applied under the anesthetic directly on the skin, without interposition of raw cotton or stockinet. Only the anterior-superior iliac spine, the os calcis and the achilles tendon required to be covered with cotton. The immediate benefits of the plaster treatment were absence of pain, rapid disappearance of shock and return of appetite. In 1,073 cases removal of the plaster for infection was necessary in only 0.75 per cent. The first plaster was retained for six weeks.

In calling for a discussion of the paper the president of the section of surgery, Mr. Cope, described it as momentous and bidding fair to revolutionize a most difficult war problem. There was general agreement as to the value of the paper, but one speaker called attention to what might seem a small disadvantage—the disagreeable smell due to saturation of the plaster with the discharges. Dr. Trueta replied that in a certain number of cases yeast obtained from breweries was applied and mitigated the smell.

The Surgical Treatment of Coronary Disease

At the Edinburgh Medico-Chirurgical Society Mr. Laurence O'Shaughnessy read a paper on the surgical treatment of coronary disease. In the cardiovascular clinic at the Lambeth Hospital of the London County Council he has performed twenty operations for cardiac revascularization. Fifteen of the patients suffered from angina pectoris. Of these five died: one on the table, another from uremia three months after the operation and three from heart failure two months after operation. All the survivors made such progress that those who were bedridden became active again and those unable to work resumed their employment. There were five patients with symptoms of cardiac ischemia other than angina and in this group no death was caused by the operation. O'Shaughnessy's operation consists of supplying a fresh source of blood for the defective cardiac circulation by transplanting a segment of omentum into the chest and grafting it to the heart (cardio-omentopexy). He first demonstrated that this was possible by experiments on greyhounds. He tied the left coronary artery, which impaired their racing powers. He later performed cardio-omentopexy on the ischemic heart and found that this restored their racing powers. He demonstrated vascular anastomosis between the omental graft and the coronary tree.

O'Shaughnessy showed that his operation imitates what may occur in disease. After coronary thrombosis in a small proportion of cases adhesions form between the infarct and the parietal pericardium. The beneficial association of pericarditis with coronary disease is illustrated by Sternberg's classic case of "pericarditis episternocardia" and Clifford Allbutt's patient, a physician who returned to active practice after a severe attack of angina complicated by pericarditis. O'Shaughnessy observed the following similar case: A man now 67 suffered from severe angina. Three years ago he had a more violent attack than any previous one and was removed to the hospital in a state of collapse. For some days his state was critical but he recovered and after some weeks in bed returned home. He gradually resumed general activity and was amazed to find that his angina had disappeared. Moritz in 1932 demonstrated by injection studies the vascularity of pericardial adhesions. In the pathologic department of the Lambeth Hospital vascular continuity between the coronary tree and the vessels of the pericardium was found in a case of pericarditis following coronary thrombosis. Another example of disease pro-

ducing a collateral circulation is furnished by what sometimes happens in cases of uterine fibroids. When a pedunculated subserous fibroid suffers partial necrosis because the blood supply through a narrow pedicle is inadequate, the omentum adheres to the affected area and not only arrests the process but provides a local circulation adequate for the growth of the tumor, which may reach an enormous size. In cardio-omentopexy another benefit is possible: the graft (which is always attached in the region of the apex) may serve as a bridge between the right and left coronary vessels.

Good results from cardio-omentopexy are not to be expected when there is gross coronary disease with occlusion at several points. Hence O'Shaughnessy considers that a case in which two or more attacks of thrombosis have occurred is probably unsuitable for operation. In cases of calcification of the coronary arteries the results have been bad. Typical indications for the operation are presented by the patient who has made an incomplete recovery from a single attack of thrombosis, progressive angina of effort, hypertensive heart failure which has reacted badly to medical treatment, and syphilitic aortitis with aortic incompetence and anginal symptoms. The contraindications to operation are age, gross structural defects in the heart and vascular degeneration in the renal or cerebral vessels.

A British Standard for Hemoglobinometers

The British Standards Institution has circulated for comment a draft British standard specification for hemoglobinometers, based on the carboxyhemoglobin method of Haldane. As a result the institution has received requests that an acid hematin method, for example Sahl's, not involving the use of coal gas or carbon monoxide, should be standardized. Before deciding to proceed with this additional standardization the institution has circulated a memorandum to medical organizations and individual practitioners interested in the subject, asking for further information.

PARIS

(From Our Regular Correspondent)

Dec. 30, 1939.

Harvey Cushing

In the meeting of the Academy of Medicine Dec. 19, 1939, Professor Guillaumin pronounced a eulogy on Harvey Cushing, a member of the academy since 1929, paying tribute to the extraordinary personality of Cushing, possessing as it did the moral and intellectual qualities of a physician at his best. He recalled the fine medical heredity of the great clinician of Boston, his professional, scientific and fraternal relations with William Osler, his travels in Europe, where he made many distinguished friends, his eminent services in the World War, his contributions and his ability as a teacher. He was, according to Guillaumin, an unerring clinician, a philosopher, educator and inspirer. All who knew him felt his courtesy, his sympathy and his deep humility.

Prevention of Thrombopenia Due to Gold Salt Therapy

In *Le Sang*, organ of the French society of hematology, Prof. Knud Secher, of Copenhagen, discusses grave accidents due to gold therapy or sodium thiosulfate. Thrombopenias occur almost altogether in patients affected with rheumatism. Secher thinks these accidents are not due to metal intoxication but to a reaction provoked by toxins liberated in the course of the treatment. Febrile reaction which he traces solely to liberated toxins may be prevented by the administration of vitamins. The vitamin deficiencies affect the same organs which are affected by gold intoxication. Accordingly, by combating vitamin deficiency protection can be given against these accidents. A mixture of vitamin A (20,000 international units), B₁ (from 750 to 1,500 international units), B₂ (from 375 to 750 Krieger-Lassen units) and C (2,500 international units) enables

Secher to prescribe the gold salt therapy with high dosage for a large number of polyarthritic persons. He never observed a case of thrombopenia. A few exanthems that occurred during treatment were rapidly aborted by the administration of vitamin C, a substance that is markedly deficient in rheumatic and tuberculous patients.

Megakaryocytes and Sternberg's Cells

The frequent use of sternal puncture in the diagnosis of blood diseases led Gustavo Pittaluga at St. Anthony's Center of Blood Research to investigate the differences between Sternberg's ganglionic cells and the megakaryocytes that exist normally in the myeloid tissue. Medlar recently raised the question of the connection of Sternberg's cells with Hodgkin's disease. He found Sternberg cells in patients with Hodgkin's disease and thinks their origin is a systematic process of megakaryocytic metaplasia of the reticulo-endothelial system. Pittaluga does not share his view. He found essential differences in a study of 100 megakaryocytes and 100 Sternberg cells in the same person. The first have an average diameter of 46 microns and attain a maximal diameter of 90; the second measure from 32 to 70 microns. The relations of the nuclear mass to the cytoplasm, the chromatophilia of the cytoplasm, the structure of the mitochondria, the structure and chromatophilia of the nuclear chromatin are not the same. The nucleolar mass and the number of azurophil granulations indicate further contrasts. Besides, Sternberg's cells are not characterized by lymphogranulomatosis. Pittaluga concludes that no etiologic connection exists between the two diseases.

Isolation of Hypertensive Substance in the Blood

The kidney of animals with permanent arterial hypertension which was induced by constricting the renal artery pours into the blood a hypertensive substance (Houssay, Fasciolo and Taquini). If such a kidney is grafted in the neck of a normal dog by uniting the renal artery and vein of the kidney to the carotid and jugular vein respectively of the normal dog, the blood pressure increases in from five to fifteen minutes. If a normal kidney is grafted in the neck of a normal dog the blood pressure of the animal does not increase (Houssay and Fasciolo 1937). The citrated plasma of the venous blood of the ischemic kidney produces a strong vasoconstriction in the Laewen Trendelenburg toad preparation. Vasoconstriction is not caused when plasma of the venous blood of the normal kidney is used (Houssay and Taquini, 1938). To obtain greater concentration of vasoconstrictive substance in the blood, Braun Menéndez and Fasciolo used venous blood from a kidney which was supplied with blood from a cardiopulmonary preparation. In an hour of functioning, the defibrinated blood loses almost all its vasoconstrictive action. If by this time the supply of arterial blood is reduced by 80 or 90 per cent and after the reduction the venous blood from the kidney is collected, it can be shown that the hypertensive and vasoconstrictive action appears immediately in the blood. An injection of a small amount of blood is given to a chloralosed dog with the aim of desensitizing the animal against shocking substances. After an hour it is found that the blood from the ischemic kidney has a hypertensive action, if it is compared with that of the kidney which has an abundant blood supply from the circuit of irrigation (control blood). The authors, in collaboration with Leloir and Muñoz, found that the hypertensive substance of the blood serum dissolves itself when the serum is treated with three volumes of acetone. The evaporated residue elevates the arterial blood pressure of chloralosed dogs. The hypertensive substance is soluble in glacial acetic acid and resists boiling as well as acid hydrolysis. It dissolves neither in ether nor in amyl alcohol. The hypertensive

substance is differentiable from renin, which does not stand boiling and does not dissolve in 75 per cent acetone. It is also differentiable from epinephrine. Braun Menéndez and his collaborators found that when renin is incubated in blood serum from a normal dog, horse or ox for fifteen minutes a vasoconstrictive substance appears in the serum which is identical with that of the blood of the kidney with acute ischemia. The substance dissolves if three volumes of acetone are added to the blood serum. The substance resists boiling and acid hydrolysis. If renin and the blood serum are separately incubated and then mixed just prior to the aggregation of acetone to the mixture, the extract from the mixture is inactive. The hypertensive substance is called hypertensine. Work carried on by the Instituto de Fisiología of the Faculty of Medicine of Buenos Aires resulted in obtaining hypertensive substances, originating in the ischemic kidney, from the blood of dogs.

Cardiac Changes in Avitaminosis

Dr. Soldati reported to the Sociedad Argentina de Biología of Buenos Aires observations on disturbances of the heart in experimental avitaminosis B₁ in rats and dogs. Bradycardia which is not modified by administration of atropine or pitressin was found in avitaminosis B₁ in rats. In dogs there are tachycardia, hypotension and dilatation of the right side of the heart. The electrocardiogram shows an exaggerated P wave, unevenness of the QR waves and sometimes inversion of the T wave. There are interfascicular edema, perinuclear vacuolization and marked vacuolization of the system of conduction in all cases. The electrocardiogram of a dog indicated recent infarct. The animal was killed. There were two anemic infarcts, some small recent infarcts and remains of old infarcts. Obstructed vessels were not found in the zone of the anemic infarct, which probably was caused by functional disturbances of the myocardial supply, namely spasm, or compression by edema, in dogs with hypotension and with muscular fibers altered by the disturbance of nutritional insufficiency. Dogs with avitaminosis B₁ react to intravenous administration of epinephrine with exaggerated hypertension and normally to acetylcholine hypotension. Pitressin produces bradycardia less acute in dogs with avitaminosis B₁ than in normal dogs. Stopping of the heart is obtained by stimulating the vagus nerve with the same acuteness as in control dogs.

Changes in Bones in Endemic Fluorosis

The presence of mottled enamel on the teeth of persons living in different regions of Argentina in which the amount of fluoride in drinking waters is abundant has been studied for years. Recently it was found that nine patients observed in Buenos Aires who came from the Pampas and other regions of the province of Buenos Aires had acute mottled enamel and skeletal alterations which varied from increased thickness of the lumbar and pelvic bones to generalized typical osteopetrosis. Drs. Capizzano, Paterson of Toledo, Megy and Valotta reported the condition in the *Revista de medicina y ciencias afines* (1, No. 4, 1939) and Maschironi, Muñoz and Reussi reported an acute case to the Sociedad Argentina de Biología. The patient died from uremia. Fluoride (0.97 per cent) was found in the ashes of the bones.

Epidemic of Psittacosis

Outbreaks of psittacosis from parrots imported from Australia are frequently reported in Argentina. The first epidemic, well studied and in which a diagnosis was made, was reported by Barros in 1929. More than ten epidemics have been studied in the last ten years. The diagnosis has been made through the Instituto Bacteriológico del Departamento Nacional de Higiene, directed by Prof. Alfredo Sordelli. Recently an outbreak took place, with twenty-five patients and nine deaths. Three physicians were victims of the epidemic; one recovered and two died.

Personals

Dr. J. J. Spangenberg was appointed president of the Departamento Nacional de Higiene to fill the vacancy left by Dr. Miguel Sussini, who retired.

The following appointments were recently made: Prof. A. J. Costa for the chair of surgical technic of the Faculty of Medicine of Buenos Aires, left vacant by the death of Prof. Guillermo Bosch Arana, and Prof. E. Castaño for the chair of urologic clinic vacated by Dr. Bernardino Maraini, who retired at the age limit.

The following physicians left recently for the United States: Dr. Hugo Chiodi with a scholarship of the Rockefeller Foundation to carry on studies in the Fatigue Laboratory of Harvard. Dr. Flaminio Vidal with a scholarship of the Rockefeller Foundation to work on the subject of neurology under Dr. S. W. Ranson in Chicago. Dr. Eduardo de Robertis with a scholarship of the Fundación Devoto of the Academia Nacional de Medicina of Buenos Aires to study histology at Chicago University. Drs. Joaquin Llacer and J. Sozzi with the scholarship of the Asociación Argentina para el Progreso de las Ciencias to study microchemistry in the New York University. Dr. Armando Parodi with a scholarship of the Rockefeller Foundation to study viruses at the Rockefeller Institute of New York. Dr. C. Galli Mainini is to study nutritional diseases with Dr. E. P. Joslin, of Boston.

Visitors

The following professors visited recently the medical centers of Argentina and gave lectures: Profs. Rovntine of New York (anesthesia), Gray Turner of London (surgery), G. Marañón of Madrid, G. G. Voronoff of Paris and George Harrop of Baltimore.

The following professors came to Argentina in exile: Professors Herlitzka of Turin, Foà of Milan, Lattes of Pavia and Morpurgo of Turin. They have neither official nor teaching positions.

Deaths

Dr. Enrique Bazterrica, an academic member, honorary professor and ex-dean of the Facultad de Ciencias Médicas of Buenos Aires and founder of modern gynecologic surgery of Argentina, aged 78, is dead.

Dr. Francisco Llobet, ex-assistant professor of anatomy and surgical medicine of the Facultad de Ciencias Médicas of Buenos Aires, aged 66, died of myocardial infarction. His collection of paintings is one of the richest in South America.

Dr. Bernardino Maraini, head of the department of urology of the Rawson Hospital and retired professor of the chair of clinical urology of the Faculty of Medicine of Buenos Aires died of myocardial infarction.

Dr. J. Salleras Pagés, assistant professor of clinical urology and head of the department of urology of the T. de Alvear Hospital, aged 52, is dead.

Marriages

ELLSWORTH H. TANNEYHILL, Chicago, to Miss Eleanor Meyer, of Mount Olive, Ill., in November 1939.

JAMES ELLIOT WALKER, Hopkinsville, Ky., to Miss Pertice Tucker, of Camp Hill, Ala., Dec. 26, 1939.

JESSE BLEASE FLOYD, Great Falls, S. C., to Miss Margaret Lewis Yongue, of Pickens, Dec. 24, 1939.

WOODROW B. ESTES, Williamsburg, Ky., to Miss Lucy Manley, of Akron, Ohio, Dec. 27, 1939.

PEARL A. TOIVONEN, Ontonagon, Mich., to Erkki Leppo, of Finland, at Detroit, Oct. 13, 1939.

EDWARD ALEX HEISE, Columbia, S. C., to Miss Imogene Hort Posey in December 1939.

CHARLES P. ROPER to Miss Cira Elizabeth Inman, both of York, S. C., Nov. 7, 1939.

Deaths

George Emerson Brewer, New York; University of Buffalo School of Medicine, 1884; Harvard Medical School, Boston, 1885; member of the Medical Society of the State of New York and the American Association of Genito-Urinary Surgeons; member and first president of the American Surgical Association and the Society of Clinical Surgeons; fellow of the American College of Surgeons; assistant demonstrator of anatomy from 1892 to 1900, instructor of surgery from 1900 to 1903, clinical lecturer, 1903-1904, professor of clinical surgery from 1904 to 1913, professor of surgery from 1913 to 1917 and since 1917 emeritus professor at the Columbia University College of Physicians and Surgeons; during the World War was director of a base hospital in France and was later consulting surgeon to the Forty-Second Division of the American Expeditionary Force; consulting surgeon to the Presbyterian, Roosevelt, Woman's, City and St. Vincent's hospitals and the Manhattan Eye and Ear Infirmary; was consultant to the Perth Amboy (N. J.) Hospital and the Muhlenberg Hospital, Plainfield; author of a "Textbook on Surgery for Practitioners and Students" published in three editions, and "Method of Surgical Diagnosis"; aged 78; died, Dec. 24, 1939, in the Harkness Pavilion of Columbia-Presbyterian Medical Center.

Henry Barton Jacobs @ Baltimore; Harvard Medical School, Boston, 1887; associate in medicine at Johns Hopkins University School of Medicine, 1896-1904; original secretary from 1904 to 1920 and member of the original board of directors of the National Association for the Study and Prevention of Tuberculosis, now the National Tuberculosis Association; past president of the Maryland Tuberculosis Association and the Laennec Society for the Study of Tuberculosis; was a trustee of the Peabody Institute, Johns Hopkins Hospital, the Harriet Lane Home for Invalid Children, the Maryland Institute, the Children's Hospital School and the Church Home and Infirmary; past president of the Hospital for Consumptives, Towson; was a member of the original board of managers of the Maryland State Tuberculosis Sanatorium; associate editor of the *Annals of Medical History*; aged 81; died, Dec. 18, 1939, of coronary occlusion.

Howard Edwin Ruggles @ San Francisco; Harvard Medical School, Boston, 1913; associate clinical professor of roentgenology from 1918 to 1927 and clinical professor since 1927, University of California Medical School; roentgenologist to St. Luke's Hospital and University of California Hospital; consulting roentgenologist to the Southern Pacific Hospital, Children's Hospital, Shriner's Hospital and San Francisco Hospital; member of the American Roentgen Ray Society; served during the World War; author, with Dr. George W. Holmes, of "Roentgen Interpretation," published in 1918, and "Urological Roentgenology," with Dr. Miley B. Wesson, published in 1936; aged 53; died, Dec. 29, 1939, of coronary sclerosis.

George Waller Hawley, Westport, Conn.; Cornell University Medical College, New York, 1899; member of the Connecticut State Medical Society and the New England Surgical Society; fellow of the American College of Surgeons; served during the World War; associate professor of surgery at the New York Post-Graduate Medical School, New York, from 1921 to 1928; attending surgeon to the Bridgeport Hospital from 1909 to 1934 and St. Vincent's Hospital, Bridgeport, from 1910 to 1917; assistant surgeon, Hospital for Ruptured and Crippled, New York, from 1908 to 1921; aged 65; died, January 1.

Robert Parke Bay @ Baltimore; University of Maryland School of Medicine, Baltimore, 1905; professor of oral surgery at his alma mater; fellow of the American College of Surgeons; past president of the Baltimore City Medical Society; chief surgeon to the Maryland General Hospital; attending surgeon to the Church Home and Infirmary; consulting surgeon to the South Baltimore General Hospital, Union Hospital of Cecil County, Elkton, and the Harford Memorial Hospital, Havre de Grace; chief medical examiner of the State Industrial Accident Commission; aged 55; died, January 1, of cerebral hemorrhage.

Edwin Lucien Perkins, Sioux Falls, S. D.; Northwestern University Medical School, Chicago, 1904; member of the South Dakota State Medical Association and the American Urological Association; fellow of the American College of

Surgeons; past president of the Sioux Valley Medical Association; served during the World War; lecturer in obstetrics at the University of South Dakota School of Medical Sciences, Vermillion; formerly physician to the state penitentiary; aged 69; on the staff of the McKennan Hospital, where he died, Dec. 10, 1939, of cerebral hemorrhage.

John Henry Mullin, Wilmington, Del.; Johns Hopkins University School of Medicine, Baltimore, 1916; member and secretary of the Medical Society of Delaware; fellow of the American College of Surgeons; past president of the New Castle County Medical Society; served during the World War; served on the staff of the Delaware Hospital in various capacities, on the courtesy staff of the Homeopathic, Wilmington General and St. Francis hospitals; aged 50; died, Dec. 20, 1939.

Charles Falkowsky Jr. @ Scranton, Pa.; University of Pennsylvania Department of Medicine, Philadelphia, 1901; member of the House of Delegates of the American Medical Association, 1936, 1938 and 1939; past president of the Medical Society of the State of Pennsylvania; fellow of the American College of Physicians; on the staffs of the Nanticoke (Pa.) State Hospital, Scranton State Hospital and the Mercy Hospital; aged 59; died, Dec. 28, 1939, of chronic myocarditis.

Dolph D. McHenry @ Oklahoma City, Okla.; University Medical College of Kansas City, Mo., 1897; member of the American Academy of Ophthalmology and Otolaryngology; fellow of the American College of Surgeons; on the staffs of the Wesley Hospital, Oklahoma City Hospital and St. Anthony's Hospital; aged 66; died, Dec. 28, 1939, at St. Anthony's Hospital, St. Petersburg, Fla., of coronary thrombosis.

Harry Clifton Burgess, Montreal, Que., Canada; McGill University Faculty of Medicine, Montreal, 1905; associate professor of obstetrics and gynecology at his alma mater; member of the American Gynecological Society; fellow of the American College of Surgeons; served during the World War; on the staffs of the Royal Victoria Hospital and Montreal Maternity Hospital; aged 56; died, January 1.

William Colegrove Tuckerman, Cleveland; University of Wooster Medical Department, Cleveland, 1905; member of the Ohio State Medical Association and the American Academy of Ophthalmology and Otolaryngology; fellow of the American College of Surgeons; aged 61; on the staff of the Glenville Hospital, where he died, Dec. 5, 1939, as the result of injuries received in an automobile accident July 30.

Theron Sparhawk Langford, Ann Arbor, Mich.; University of Michigan Department of Medicine and Surgery, Ann Arbor, 1902; member of the Michigan State Medical Society; past president and secretary of the Washtenaw County Medical Society; served during the World War; formerly member of the city board of health; aged 67; died, Dec. 20, 1939, in the University Hospital of coronary thrombosis.

Harry Locke Paddon, North West River, Labrador; L.R.C.P., London, and M.R.C.S., England, 1911; a medical missionary for many years associated with the work of Sir Wilfred Grenfell in Labrador; head of the hospital school and industrial work of the Grenfell Foundation at North West River, and Indian Harbor, Newfoundland; aged 58; died, Dec. 24, 1939, in the Bryn Mawr (Pa.) Hospital.

Joseph Numa Roussel @ New Orleans; Tulane University of Louisiana School of Medicine, New Orleans, 1896; formerly professor of dermatology at the Louisiana State University Medical Center; for many years dermatologist in charge of the Touro Infirmary, and senior visiting physician, division of dermatology, Charity Hospital; aged 68; died, Dec. 15, 1939, of angina pectoris.

Oren Mechling Kramer, Millersport, Ohio; Starling Medical College, Columbus, 1897; member of the Ohio State Medical Association; past president of the Fairfield County Medical Society; formerly physician to the state penitentiary; aged 66; died, Dec. 18, 1939, in the White Cross Hospital, Columbus, of coronary thrombosis.

Lee Humphrey, Malta, Ohio; Medical College of Ohio, Cincinnati, 1888; member of the Ohio State Medical Association; member and past president of the state medical board; and for many years member of the county school board and of the school board of Malta; bank president; aged 75; died, Dec. 30, 1939, of angina pectoris.

James H. Oakley @ Surgeon, U. S. Public Health Service, Evansville, Ind.; Northwestern University Medical School, Chicago, 1891; entered the U. S. Public Health Service as an assistant surgeon March 21, 1893, and retired Nov. 1, 1929; aged 70; died, Dec. 21, 1939, of hypertension and cerebral hemorrhage.

Heber E. Butts * Surg., Lieut. Commander, U. S. Navy, retired, San Diego, Calif.; George Washington University School of Medicine, Washington, D. C., 1904; entered the navy in 1906 and retired July 1, 1937, for incapacity resulting from an incident of service; aged 62; died, Nov. 9, 1939.

Siegel Charles Frankel * Louisville, Ky.; University of Louisville Medical Department, 1906; associate clinical professor of medicine at his alma mater; on the staffs of the Louisville City Hospital, Jewish Hospital and the Kosair Hospital; aged 59; died, Dec. 27, 1939, of arteriosclerosis.

Simon Peter Schroeder, Nashville, Ill.; Hospital College of Medicine, Louisville, Ky., 1887; member of the Illinois State Medical Society; formerly secretary of the Washington County Medical Society; at one time county coroner; aged 78; died, Dec. 24, 1939, of coronary thrombosis.

George Marquet Phillips, Eau Gallie, Fla.; College of Physicians and Surgeons, Baltimore, 1887; at one time professor of genito-urinary surgery at the Barnes Medical College, St. Louis; aged 77; died, Dec. 25, 1939, in the Riverside Hospital, Jacksonville, of cerebral hemorrhage.

Henry Wise Lyon, Windsor, N. C.; University of Pennsylvania School of Medicine, Philadelphia, 1918; formerly county health officer, member of the county board of health and member of the school board; aged 49; died, Dec. 16, 1939, of chronic myocarditis and hypertension.

Victor Arthur Robertson * Brooklyn; College of Physicians and Surgeons, Medical Department of Columbia College, New York, 1883; fellow of the American College of Surgeons, consulting surgeon to the Coney Island and Harbor hospitals; aged 78; died, Dec. 21, 1939.

Leon Algernon Tancil * Chicago; Howard University College of Medicine, Washington, D. C., 1921; on the staffs of the Central Free Dispensary and the Provident Hospital; aged 49; died, Dec. 7, 1939, in the Presbyterian Hospital of amyotrophic lateral sclerosis.

Louis John Frederick Staack, Brooklyn; College of Physicians and Surgeons, Medical Department of Columbia College, New York, 1895; aged 65; died, Dec. 25, 1939, in the New York Polyclinic Medical School and Hospital, New York, of coronary occlusion.

Roy Sumner Stearns, Portland, Ore.; Harvard Medical School, Boston, 1905; member of the Oregon State Medical Society; fellow of the American College of Surgeons; on the staff of the Portland Sanitarium; aged 62; died, Dec. 12, 1939, of coronary occlusion.

William Henry Steele, Montpelier, Ohio; University of Michigan Department of Medicine and Surgery, Ann Arbor, 1903; for many years member of the board of education; served during the World War; aged 66; died, Dec. 22, 1939, of coronary sclerosis.

Luther Throngberry Young, Florence, Ala.; Emory University School of Medicine, Atlanta, 1917; member of the Medical Association of the State of Alabama; served during the World War; aged 50; died, Dec. 26, 1939, of a self-inflicted bullet wound.

James Jett McCormick, Norfolk, Va.; University of Virginia Department of Medicine, Charlottesville, 1892; formerly city health officer; city bacteriologist and secretary of the board of health; aged 71; died, Dec. 21, 1939, of bronchiectasis.

George Lewis Johnson, Morristown, N. J.; Baltimore Medical College, 1901; member of the Medical Society of New Jersey; served during the World War; for many years police surgeon; aged 67; died, Dec. 12, 1939, of cerebral arteriosclerosis.

Nathaniel Robinson, Brooklyn; New York Homeopathic Medical College, 1885; fellow of the American College of Surgeons; attending surgeon to the Carson C. Peck Memorial Hospital; aged 78; died, Dec. 13, 1939, of cerebral hemorrhage.

Leonard Schreifels, Granite City, Ill.; St. Louis College of Physicians and Surgeons, 1899; member of the Illinois State Medical Society; past president of the Madison County Medical Society; aged 73; died, Dec. 27, 1939, of heart disease.

Warren G. Young, Port Arthur, Texas; University of Louisville (Ky.) Medical Department, 1891; member of the State Medical Association of Texas; aged 70; died, Dec. 12, 1939, in St. Mary's Hospital of coronary disease.

James T. Biggerstaff, Wabash, Ind. (licensed in Indiana in 1903); member of the Indiana State Medical Association; past president of the Wabash County Medical Society; aged 85; died in December 1939 of chronic myocarditis.

Frank A. Townsend, Orange, Mass.; University of the South Medical Department, Sewanee, Tenn., 1898; aged 70; died, Nov. 9, 1939, in the Franklin County Hospital, Greenfield, of cerebral hemorrhage and arteriosclerosis.

John E. Handy, Caro, Mich.; Detroit College of Medicine, 1887; member of the Michigan State Medical Society; formerly member of the state board of registration in medicine; aged 80; died, Dec. 1939, of chronic myocarditis.

Joseph Harrison Shelton * Kingsville, Texas; University of Virginia Department of Medicine, Charlottesville, 1905; fellow of the American College of Surgeons; aged 56; died, Dec. 23, 1939, of coronary thrombosis.

Detlef Marius Ferdinand Krogh, Philadelphia; Jefferson Medical College of Philadelphia, 1896; member of the Medical Society of the State of Pennsylvania; aged 72; died, Dec. 3, 1939, of arteriosclerotic heart disease.

James Perry Vickrey, Steele, Mo.; St. Louis College of Physicians and Surgeons, 1917; member of the Missouri State Medical Association; aged 55; was found dead, Dec. 17, 1939, of stab wounds inflicted by robbers.

Lewis Lowe Neblett, Clarksville, Tenn.; Vanderbilt University School of Medicine, Nashville, 1901; member of the Tennessee State Medical Association; aged 73; died, Dec. 25, 1939, of coronary occlusion.

Emil Philip Wilhelm Richter * Saginaw, Mich.; Saginaw Valley Medical College, 1900; served during the World War; formerly county coroner; aged 64; died, Dec. 21, 1939, in the Saginaw General Hospital.

Arthur Asbra Shaw, Clinton, Maine; Medical School of Maine, Portland, 1891; member of the Maine Medical Association; aged 75; died, Dec. 15, 1939, in Concord, N. H., of carcinoma of the prostate.

James Cowan Storie, Ashburnham, Mass.; College of Physicians and Surgeons, Medical Department of Columbia College, New York, 1884; aged 84; died, Nov. 1, 1939, of chronic myocarditis.

Charles Franklin Martin, Boonville, Ind.; Louisville (Ky.) and Hospital Medical College, 1908; member of the Indiana State Medical Association; aged 53; died, Dec. 18, 1939, of coronary occlusion.

Charles Bond Warner, Port Henry, N. Y.; Bellevue Hospital Medical College, New York, 1880; past president of the board of education; aged 85; died, Nov. 25, 1939, of influenza and myocarditis.

William Boyles Staples, Bladon Springs, Ala.; University of Nashville (Tenn.) Medical Department, 1896; aged 69; died, Dec. 13, 1939, in Mobile, of chronic nephritis and cerebral hemorrhage.

Edward Carson Abbott, Omaha; State University of Iowa College of Homeopathic Medicine, Iowa City, 1899; aged 63; died, Dec. 16, 1939, in the Lutheran Hospital of chronic myocarditis.

Eugene John Rooney, Chicago; University of Illinois College of Medicine, Chicago, 1927; served during the World War; aged 44; died, Dec. 29, 1939, of massive hemorrhage and duodenal ulcer.

George Swan Iddings, Euclid, Ohio; Cleveland Medical College, 1897; University of Wooster Medical Department, Cleveland, 1899; aged 88; died, Dec. 10, 1939, of arteriosclerosis.

Harry Thorne, Dayton, Ohio; Medical College of Ohio, Cincinnati, 1895; formerly member of the board of education; aged 66; died, Dec. 18, 1939, of chronic myocarditis.

Victor Clyde Laughlin, Lancaster, Calif.; Western Reserve University Medical Department, Cleveland, 1898; aged 66; died, Nov. 26, 1939, of coronary thrombosis.

Fred C. Cade, Chicago; Chicago Medical School, 1919; on the staff of the Provident Hospital; aged 53; died suddenly, Dec. 11, 1939, of coronary thrombosis.

Cora L. Emery Reed, Rock Island, Ill.; Hahnemann Medical College and Hospital, Chicago, 1884; aged 81; died, Dec. 3, 1939, of chronic myocarditis.

Harry Wilfrid Gaddess * Baltimore; Baltimore University School of Medicine, 1900; aged 60; died, Dec. 2, 1939, of cerebral hemorrhage.

Roswell Dwight Cruikshank, Goose Creek, Texas; Rush Medical College, Chicago, 1905; aged 63; died, Dec. 20, 1939, of cerebral hemorrhage.

Yves Lefebvre, Montreal, Que., Canada; University of Montreal Faculty of Medicine, Montreal, 1924; aged 41; died, Dec. 20, 1939.

Bureau of Investigation

NORMAN BAKER

Norman Baker, cancer quack of Muscatine, Iowa, and Eureka Springs, Ark., was found guilty on January 23, of using the United States mails to defraud. A few days later he was fined \$4,000 and sentenced to four years in the penitentiary. This 56 year old, white haired, nonmedical founder of the Baker Hospital has been the subject of numerous reports, both in these columns and in the editorial pages of *THE JOURNAL* and in *Hygia*, the health magazine. Now that he is for the first time quite incommunicado for a number of years, his history may be reviewed.

In a book called "The Throttle, A Fact Story of Norman Baker," by Alvin Winston, we find that "it took half a century of magnificent living on Norman Baker's part to make the story," and that the reader, when he finishes the story, is supposed to be inspired to write the following letter to his Congressman:

"Dear Sir: THE THROTTLE, A Fact Story of Norman Baker, charges that the radio trust did so and so; the medical monopoly, the American Medical Association, did so and so (fill in the details your own way); the aluminum trust and the rest did so and so. If this is untrue, send Norman Baker to jail. If it is true, send them to jail. I demand an investigation, at once. Or I'll vote for a man who will investigate. Sincerely,"

One Clement Wood wrote a foreword for this book, in which he stated:

"I admire Franklin Roosevelt so much, for his magnificent start in cleaning up the mess the Republicans had plunged us into, that I shall not nominate Baker for President until Roosevelt is through with the job. My slogan is, Norman Baker as Roosevelt's successor!"

Reference to the text indicates that Norman Baker was born in Muscatine, Iowa on Nov. 27, 1882, and was one of nine children of a family of German descent. It is clearly indicated in "The Throttle" that this is not a large city—"but it was the birthplace of Norman Baker; and Bethlehem is smaller yet."

Again according to "The Throttle," Baker received his education at the East Hill School and the Third Ward School and subsequently attended high school for a year and a half, at which time he apparently went to work in a machine shop. Later, according to the same source, he obtained a position which was offered to his brother in a button factory by claiming that the brushes on the motor were not properly adjusted. According to "The Throttle:" "Now Norman Baker knew that there was nothing wrong with the brushes; but he was an instinctive salesman, and psychologist enough already to be sure that McDermott didn't know a brush from a pulley. He thought it would impress the potential employer. It did. The boy got the job."

"The Throttle" indicates that Baker believed in his own horoscope and the encouraging compliments which it paid to him. The author of "The Throttle" claims that "he once told me earnestly that he was sure that the moon, at least, had an effect on people; else why was it that, near the north pole, where the day is six months long, and the night as long, the women have only one menstrual period a year?"

A number of years later Baker was busy promoting a mind-reading act that was continually going broke, according to "The Throttle," which states that Baker cured himself of pneumonia with the mental determination to get well and a dish of ice cream. His principal in his "act" featuring "mental therapeutics" was known as Madame Tangley. Subsequent to this Baker is said by Winston to have invented and manufactured the "Calliaphone," which was promoted by the Tangley Company, Muscatine, Iowa. The instrument was subsequently heard nightly over XENT.

If one may believe "The Throttle," Baker at that time waged a successful war against the local power and light company at Muscatine, and his activities were supposed to have resulted in the development of a municipal plant which put the company out of business.

His Calliaphone activities were burned out one night, and he started an art correspondence school. Comments "The Throttle:" "It is no wonder that the American Medical Association publicly branded him as a Jack-of-all-trades; to the one-trade mind, such as that of a medical man, there is something suspicious about a man who can do everything, and everything well. No doubt Baker will proudly accept the charge, if to it is added the summary of what he did in all these trades: so that the indictment will then run, Norman Baker, Jack of all trades, and master of all."

About this time he was said to have some rather unusual ideas as to the treatment of shell shock. In the meantime he had reestablished the Calliaphone business on the profits obtained from the correspondence school course in art and began his activities in the radio field, which subsequently developed into Station KTNT at Muscatine. According to "The Throttle" he fought A. T. & T. and what he refers to as the "Radio Trust." His activities in the radio field led him into many other businesses. Because the crowds who attended the programs that were given over the radio complained of the food they obtained in Muscatine, he opened KTNT Cafe. Because they were unable to get gasoline, he opened KTNT Oil Station and, according to "The Throttle," successfully bucked Standard Oil. When the visitors to KTNT complained of blow-outs, he started the manufacture of a tire called The Tangley Pure Gum Rubber Tire, and "other products were added. A mail-order catalog was issued, which Baker still asserts contained more real bargains, more value for the money, than any catalog issued in the United States from that day to this."

He was also operating TNT Magazine Publishing Company, the Baker Press, which printed "The Throttle," and the Baker Cancer Hospital, in addition to the Tangley Correspondence Art School, the Baker Advertising Agency, the KTNT Chain Stores at Muscatine and Davenport, the Western Drug Company and the Mid-West Free Press, in addition, of course, to the Tangley Company, which manufactured the Calliaphone.

He was active in 1929 in the anti-aluminum ware campaign, and, if "The Throttle" can be believed, he first took up with cancer when he was "on the alert to find some matters of sensational public interest" and "at this time Baker, like most Americans, had been led by the pronouncements of the American Medical Association and their subsidiaries the State Boards of Health, to believe that cancer was one of the most dreaded of all diseases and was incurable." He became convinced that he had encountered a real cure and that if this could be proved, TNT would carry a story "Cancer Is Curable," if not, a story entitled "Cancer Doctor a Fake."

Apparently Baker had been previously connected with a varicose vein treatment and, with the inventor, Dr. Barewald, opened the Tangley Institute at Muscatine, Iowa, for the treatment of this condition. Subsequently, according to "The Throttle," he reviewed the evidence which became available as a result of his further investigations, and "the December 1929 issue of TNT . . . came out with an article revealing all these facts, headed by the proud title 'Cancer is Conquered.'" According to "The Throttle," he had arrived, from his painstaking tests, at the conclusion that "we quote from the December 1929 TNT—"the worst cases of cancer can be permanently cured. He challenges the world to investigate and disprove this broad and positive statement by the facts. All that he asks is open-minded investigation."

In "The Throttle" we find the statement: "Some said Baker was out for Governor; others, that he aspired to shoulder the Senatorial toga. Baker has no political ambitions . . ." And eight pages further along, in referring to some difficulty that Baker had encountered, it is stated: "There was only one good answer for it: for Baker to accept the proposition that had been made to him, that he run for Governor of Iowa, on the Farmer-Labor ticket." And a few sentences further along: "Next to the two major parties, Baker carried practically every county in Iowa." As nearly as can be determined, this sentence indicates that he ran third in those counties. According to the Associated Press, he was also subsequently a candidate for senator in Iowa in 1936.

One more reference to "The Throttle" is in order. Says the author: "If I were to have the power to dictate the future chapters of his life, I think I should head them:

Chapter XXVIII. License of KTNT Restored; Baker Operates the Two Greatest Stations in All Radio History.

Chapter XXIX. Dissolution of the A. M. A., as a Monopoly, after Government Investigation.

Chapter XXX. Dissolution of the Chain Radio Monopoly, and Appointment of Impartial Federal Radio Commission.

Chapter XXXI. Selling of Aluminumware for Kitchen Use Made a Federal Penitentiary Offense. Poisonous 'Purifying' of Water Forbidden Hereafter.

Chapter XXXII. Norman Baker Elected President of the United States, on Farmer-Labor Ticket. Perhaps of the United States and Mexico. But perhaps that is looking too far into the future. But Jim the canary is whistling his heart out, right over the immense hexagonal desk; and the sturdy little Napoleon is leaning over towards me earnestly, "Now, Alvin, the way this book ought to end, is—"

Now the license of KTNT has not been restored to date; the A. M. A. has not been dissolved; chain radio is neither a

ciation against the promotion of medical fraud. THE JOURNAL pointed out that the viciousness of Baker's broadcasting was not the lies he told about the American Medical Association but that he induced sufferers from cancer to resort to his nostrum in place of obtaining proper treatment.

In the next issue of THE JOURNAL it was pointed out that the Des Moines Register had reprinted the previous article relative to Baker and had made an investigation of its own which established the utter falsehood of the claims made by him in his radio talks. The Register revealed many deaths from cancer among the Baker clientele and revealed the menace of Bakerism to be his vicious influence against modern scientific diagnosis and treatment and modern health work. Baker's reply was to state that he was being persecuted by the "Medical Trust," that he was benefiting 25 per cent of cancer, and that the Des Moines Register was "cowardly, contemptible and dirty."

That same year record was obtained of an individual who had been told at the Baker Institute that he had cancer of the chin and who stated that the Baker Institute "asked \$250 for the cure and \$240 to \$360 hospital care; also they charged \$10 examination before they would look at me. At the university hospital they charged \$49.50 in all and I was there just twelve days!" His treatment at the hospital referred to (University of Iowa College of Medicine) was entirely successful. Incidentally, the patient's condition was not cancer of the chin but what is commonly known as "barbers' itch."

The following year the Bureau of Investigation published an article in THE JOURNAL entitled "Norman Baker's Radio Station KTNT." It was stated that Baker was suing the American Medical Association for half a million dollars for alleged libel. In the meantime Norman Baker had applied for renewal of his broadcasting license, but it was denied because Mr. Yost, Chief Examiner for the Federal Radio Commission, pointed out that Baker had failed to establish that a renewal of his license would be in the public interest, convenience or necessity, that in serving the public with radio programs the station had subordinated the interests of the listening public to the interests of the licensee, and that therefore the granting of the application for renewal would not serve the public interest, convenience or necessity and therefore recommended that renewal be denied. Subsequently an extension was obtained by Baker, but he was definitely ordered off the air by June 5, 1931.

The case of Norman Baker versus the American Medical Association, after some four weeks of court proceedings, resulted in a verdict for the Association. Evidence was introduced in the trial justifying the statements on which libel was charged. At that time THE JOURNAL pointed out that "the evidence brought forth arouses pity for the situation that can permit the poor, the sick and the ignorant to be exploited. Justification by the courts of the condemnation given by THE JOURNAL to such exploitation repays but in small measure those who have suffered. The only answer that charlatanism can make to the publication of facts is a suit for libel. In its efforts to protect the public, THE JOURNAL and the American Medical Association have not been rarely compelled to respond to such suits. Fortunately, the Association is able to answer adequately. The appreciation of the medical profession and of the public is tendered to all those who have cooperated to bring to a successful issue the case of Norman Baker versus the American Medical Association." The following issue of THE JOURNAL carried a five page report of this case.

Later the same year THE JOURNAL published an editorial entitled "Voices Across the Rio Grande," which referred to the John R. Brinkley radio station, XER, and stated that it was anticipated that Baker would also operate from across the river. In a report on "Dr. J. L. Statler and Norman Baker" published by the Bureau of Investigation in THE JOURNAL for July 31, 1937, it was noted that Baker was operating Station XENT at Nuevo Laredo, Mexico, and was again applying for the right to open a station in Muscatine. In the meantime Baker was operating hospitals at Muscatine and Laredo, Texas, subsequently moving the Laredo institution to Eureka Springs, Ark. Furthermore, the Federal Communications Commission decreed that the manufacture of reproductions in this country and their transportation to a foreign country for the purpose of

Greatly reduced reproduction of the cover of Norman Baker's Magazine TNT. In it, and in reprints of it, Baker declared that cancer had been conquered, and published details of alleged cures which investigation proved to be not cures but deaths.

monopoly nor has it been dissolved; the selling of aluminum ware is not a penitentiary offense, because aluminum ware is not poisonous, as Baker has stated it is; and Norman Baker is in jail with little likelihood of ever becoming president of either the United States or Mexico, let alone both. Incidentally, Baker was not released on bond, because the judge stated that if he were in Baker's shoes he would skip the country if he were out on bond, especially if he had as much financial interest in another country as Baker has in Mexico.

THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION first reported Baker's activities in the issue of April 12, 1930, under the title "Broadcasting Bunk." It was pointed out that over KTNT of Muscatine, Iowa, Baker was promoting the old Hoxsey "cancer cure," which was responsible for many deaths in Taylorville, Ill., a number of years before; that he was claiming that the American Medical Association had offered him a million dollars in order to force the remedy off the market, and that he was using much of the scandalous insinuation that proprietary manufacturers used back in 1905, when they first attempted to hinder the battle of the American Medical Asso-

being broadcast from a foreign station so that they were received consistently in the United States was a violation of the regulations of the Commission. This decision, however, was subsequently reversed.

On April 15, 1939, THE JOURNAL published an editorial concerning the use of Baker's "cancer cure" in New Zealand and stated that an investigating committee reported:

"We have no doubt that Baker's fluid is a powerful sclerotic agent and can cause great local destruction. Compared with surgical treatment, destruction by a sclerosing or caustic fluid seems like a reversal to the treatment of the Middle Ages, causing unnecessary mental distress, delayed healing and increased risk of septic infection. We have had no evidence whatever to show that Baker's fluid has any selective powers in the destruction of cancer cells."

Under the heading "Arkansas Medical News" in THE JOURNAL for Sept. 30, 1939, it was noted that "Norman Baker, who moved his 'cancer cure' business to Arkansas after being accused of quackery in Iowa [he was fined \$1,000 and sentenced

if they fail to issue you a card each year. They didn't do a dam thing to Stat did they and I bla-bla it over the radio and told them old Stat would go right along and practice in Iowa without your dam old card, didn't I tell them that—didn't he work all year—didn't he get his card. To hell with that dam bunch of rats, they don't bludd [bluff?] me one minute . . ."

The identity of the author is self evident. "Stat" is presumably J. L. Statler, M.D. Statler and R. A. Bellows, the superintendent of the Baker Hospital, were also sentenced in this case—Statler for one year and one day and Bellows for two years.

The defense offered twenty-seven witnesses in support of the contention that Norman Baker and four associates had acted in "good faith" in advertising cures for cancer and other diseases through the mails and over the radio. Several of the witnesses admitted on cross-examination that they had come to testify at the trial in response to telegrams sent them by Norman Baker at Little Rock. Others said they had had letters from the Baker Hospital. One individual told the court that he had volunteered

Cancer Is Conquered

Article I

CANCER is conquered. The greatest discovery in medical science in years—a positive cure for cancer, that dread disease which has taken toll of millions of lives, caused thousands to com-

Photo No. 1

mit suicide and driven other thousands to insanity—has been revealed by an investigation conducted by Norman Baker, publisher of TNT magazine and owner of the Norman Baker Enterprises and radio station XTNT, who was assisted by a physician and member of his staff.

Seeing is believing. Mr. Baker and his fellow investigators have seen with their own eyes enormous and malignant cancers in advanced stages of growth rapidly yield to a new and painless treatment, soften and disappear. They selected the cancer cases themselves for observation after they had determined beyond any doubt that they were authentic cases of cancer. They have watched these true cases of cancer under treatment and have seen the cancers grow smaller and pass away.

Will Spread the Truth As a result of these investigations, Mr. Baker is ready to announce to the world that a treatment has been found that permanently cures cancer.

The investigation has covered several months of painstaking observation of selected cases. It will be continued for sometime and results will be reported in TNT magazine. The results observed to date have thoroughly convinced Mr. Baker that cancer has been conquered. He has decided, in consequence, to place TNT magazine and radio station XTNT wholeheartedly and unreservedly behind a campaign to spread this truth throughout the world.

Importance of the Discovery

It is hardly necessary to explain the importance of this discovery. Cancer is one of the most painful, hideous and terrible diseases known to man. It is advancing at an alarming rate in its inroads on mankind. One person in every ten now has incipient or malignant cancer. Unless it is checked by medical science its rapid spread will make it the major disease menace to the human race. Statistics show that more than 100,000 people die yearly of cancer. Science is engaged in a literal war of defense against it and is steadily losing ground. As a result, cancer has become one of the chief concerns of medical science. No disease claims more attention and caused more scientific investigations. A positive and permanent cure has been found for this disease. A priceless blessing has been conferred on the human race. One of the greatest causes of human suffering will soon be removed and the hearts of millions will be gladdened.

The frightful nature of this disease is indicated by the pictures on this page. Photo No. 1 illustrates cancer of the face. The photograph was made so that the patient's features would not be recognized. A cancerous growth like this eats its way from the outside into the mouth so that the patient is not able

to eat solid food and subsists on liquid food until the end comes.

Photo No. 2 shows a cancerous breast, with one breast removed. This is the most prevalent form of cancer. Men will never realize the untold agony women suffer from it. Photo No. 3 shows another cancerous breast. Here the cancer is spreading to the upper part of the shoulder and under the arm.

What Caused the Investigation

The investigation that revealed the great discovery was started by Mr. Baker after a number of seemingly miraculous cures of very severe cases of cancer had been brought to his attention. The physician who was effecting these remarkable cures had encountered determined opposition from his profession and was having a hard fight to retain his license. This situation appealed to Mr. Baker as demanding attention. Was a valuable truth about to be suppressed because it might disturb or upset established methods and an organized and entrenched interest? An im-

Photo No. 2

tial investigation ought to reveal the truth. A successful investigation would either estab-

lish the value of the alleged discovery and thereby confer a priceless blessing on humanity, or else it would expose the treatment as a fake and the perpetrator as a charlatan, thus saving

Photo No. 3

ing numberless prospective victims from losing their money uselessly or to their physical injury. Added to these motives was Mr. Baker's motive as a publisher keenly on the lookout for a feature article.

Real Test Planned

The investigation was started without bias or prejudice either for or against the alleged cure, but solely for the purpose of revealing the truth. The first step was a visit with the physician who had the cancer formula. The interview impressed the investigators very much. Patients were seen in various stages of the treatment and the evidence they supplied as to the efficacy of the treatment was overwhelming. The formula was not only being applied to the cure of cancer, but to the cure of other diseases arising from bad nutritional conditions, such as diabetes, Bright's disease, tuberculosis, colitis, stomach ulcers, gall stones and rheumatism.

The physician gave the investigators many names and addresses of patients whom he stated had been cured for years and were now living without a trace of cancer. He asked the investigators to interview them. Acceptance of this offer was deferred for the time being in favor of a test that would be of a much more fundamental and convincing nature. The testimony alone of alleged former patients would not be conclusive, as testimonials are often obtained by payments or personal influence.

As the basis of the investigation, Mr. Baker proposed that he select two test patients for the treatment after it had been positively determined that they had cancer. The actual results obtained from the treatment of these selected patients would fairly gauge the value of the remedy. He proposed to obtain these patients by giving talks over his radio station, XTNT, in which he would call for volunteers for a test treatment for cancer. The selection was to be made, if possible, from patients coming from different parts of the country, showing cancer in different stages of growth, and in different parts of the body. In addition Mr. Baker and his assistants would avail themselves of the offer to interview or write to patients said to have been cured years ago and who had not suffered the return of the cancer.

Five Patients Selected

This challenge was immediately accepted. A stipulated price was agreed upon for the test patients, and Mr. Baker agreed to pay the expenses of some of the patients. In the accompanying pictures are presented photographs of the test patients selected showing the cancerous growths. In the January issue of TNT pictures of cured patients together with complete

data will be presented. We will not publish the names and addresses of the patients as they do not wish undue publicity, but assure our readers that the original photographs, letters and affidavits connected with the investigation, and the identity of the patients, are a matter of record, and will be furnished any government or private institution, physician, medical group or association desiring to investigate for the purpose of giving the truth to the public.

As a publisher, Mr. Baker does not desire credit for being the first to reveal this discovery to the world. He has, therefore, sent copies of this article to the press and has limited the newspapers to verify the facts claimed as a result of his investigation, or use all or any part of this article.

First Patient Treated

The first patient to respond to the radio call for the test treatment was a woman who lives 25 miles from Muscatine and was suffering from a very bad abdominal cancer. She had been treated by local physicians and the Medical College of the State University of Iowa for cancer. As a last resort radium

Photo No. 4

was used. The result of these radium burns are shown in the photograph of this woman, marked Photo No. 4. This radium burn was about four inches long and when spread out was

to one day in the Muscatine county jail following his plea of guilty to an indictment charging him with practicing medicine without a license, surrendered to the United States marshal on a federal indictment charging him with using the mails to defraud." The conclusion of this case is referred to in the opening paragraph above. Others who have been associated with Baker for a number of years and who were indicted along with him will be the subject of an early article in these pages.

The trial was quite suggestive of the trial of Baker versus the American Medical Association and, needless to say, the testimony of the experts was very similar. Evidence was introduced to show that Baker had expected to make a million in a year's time, that he employed the word "suckers" in this connection, and that former employees testified that they had never seen any cancer cured. According to an Associated Press release from Little Rock, Ark., the following note was entered in evidence:

"Get a belly-fll of courage and nerve and tell the first _____ to go to hell that tells you he will cancer [cancer?] your license. Never yet as any Dr. even been cancelled or revoked and what in hel do you care

to come to testify "to help Mr. Baker out." Needless to say, the evidence of these individuals was riddled and failed to stand up as adequate evidence of the usefulness of the procedures employed by Baker.

Baker's "experts" included Dr. E. M. Perdue and Dr. Charles Loffler. Both have been subjects of adverse reports by the Bureau of Investigation in these pages. Again and again the same names appear whenever charlatans are called to account in the courts. Is there not an old proverb about "Birds of a feather"? The government experts included Dr. Max Cutler of Chicago and Dr. Francis Carter Wood of New York City. They testified without remuneration and the public and medical profession owe them appreciation.

A few days after being found guilty, Baker was fined \$4,000 and sentenced to four years' incarceration. A motion for a new trial was denied.

Four thousand dollars isn't a lot of money for a Baker, and four years isn't an eternity, but it meets the situation for the present admirably. Most admirably!

Correspondence

PROTEST AGAINST COMMERCIAL EXPLOITATION OF A SCIENTIFIC CONTRIBUTION

To the Editor:—In my mail January 3 I received a form letter on the stationery of Sutliff & Case Company, Inc., of Peoria, Ill., a circular advertising "Thio-Cara Compound and Thiocyan-Tabs" and what purported to be a transcript of a ten minute address which I gave before the Inter-State Post Graduate Medical Association meeting held in the Palmer House, Chicago, Nov. 1, 1939, on the subject "Experiences with the Surgical Treatment of Hypertension."

On the same date, on the advice of the Bureau of Legal Medicine and Legislation of the American Medical Association, I wrote this company calling attention to the fact that it had used my name in connection with advertising its product without my knowledge or my consent. I informed the company that the further use of my name in that connection was forbidden and that it must stop such use immediately.

I also stated that the material which purported to be a stenographic report of my address before that meeting was not submitted by me to any of the officers of that association nor was any other paper submitted to them; that the material was never seen by me prior to January 3 and that it had never been corrected or approved by me; that the statement that ". . . we have obtained his material and are attaching same hereto; . . ." thus indicating thereby that it obtained that material from me, was entirely a false statement.

I have sent all of the correspondence involved to the Council on Pharmacy and Chemistry and the Bureau of Legal Medicine and Legislation of the American Medical Association, including the most recent demands by me on this company to send a letter of retraction dictated by me and signed by the president of Sutliff & Case Company, Inc., to each of the doctors previously circularized.

Perhaps you will decide that this type of action by a drug company, which is indefensible, should be called to the attention of other physicians and surgeons.

LOYAL DAVIS, M.D., Chicago.

VITAMIN DEFICIENCIES AND RESTORED FOODS

To the Editor:—The publication in THE JOURNAL, Dec. 9, 1939, by the Council on Foods of Dr. Cowgill's article on The Need for the Addition of Vitamin B₁ to Staple American Foods marks an important step in this field and deserves the attention of American physicians. While evidence of deficiency of this factor in the diets of the Western nations has been accumulating during the past ten years, a quite properly conservative attitude toward these claims has been maintained by the Council. In publishing this article the Council has evidently decided that the facts are now so well established as to warrant their presentation as authoritative, and that they are of such importance that the medical profession and the public should be made aware of them.

Chief among these facts are the following:

1. Changes in milling practice and in the consumption of cereal products during the past hundred years have reduced the vitamin B₁ content of "good" diets from over 1,000 international units daily to 500 units or less. The latter figure does not furnish a desirable margin of safety and for some individuals, and in certain conditions, is definitely suboptimal.

2. A large part of our population subsists regularly on diets well below the 500 unit level and definitely in the deficiency zone.

3. Clinical experience with supplementary vitamin B₁ administration confirms strikingly the thesis that many persons suffer from a chronic shortage of B₁.

4. It is desirable that means be found for augmenting the vitamin B₁ intake of the population as a whole.

Dr. Cowgill's able discussion of this situation leads him to conclude that "prosecution of a program for fostering addition of vitamin B₁ to staple American foods according to the principles discussed in the present report would be definitely in the interests of the public." It is at this point that his proposed program, that of adding thiamin to wheat flour and cereal products, calls for critical examination and discussion. The embryo of grain is a highly complex reservoir of materials required for the growth and development of the plant, comparable as such to egg yolk, and as little understood. Furthermore, our knowledge of the essential dietary factors is far from complete. It happens now to be known that loss of this part of the cereal entails a nutritionally significant loss of vitamin B₁ from the diet. One is not justified in assuming that it entails no other significant losses until our knowledge of nutrition is more advanced than it now is. To propose solving this problem by adding thiamin to the diet is to evade the very real possibility that this measure will not solve the whole problem but will rather delay the search for a better solution.

Until all the factors lost in milling are known and it is known that each of the others is adequately supplied by other foods, the logical solution of the problem presented is the restoration of the grain embryo itself to the diet.

How this is best to be done is a matter for discussion, but there can be no question as to its desirability. Modern technology should be able to find a way to produce whole grain flours with satisfactory keeping qualities, to develop more useful whole grain products and to educate the public to use them. There are stable preparations of cereal embryo on the market for supplementing the diet; while these may be economically beyond the reach of the poor, a wider use might reduce their cost to a level which would make them more generally available.

Cereal germ is cheap and plentiful. To discard it from our human food supply is nutritional wastage on a huge scale, and one is not justified in assuming that the addition of thiamin alone to the present food supply will compensate for its loss. How to get it back into the diet is a technical problem which should not be impossible of solution and it would seem to be a more desirable objective than that proposed by Dr. Cowgill.

HENRY E. MARKS, M.D., New York.

THE PLUMMER-VINSON SYNDROME

To the Editor:—The editorial entitled the "Plummer-Vinson Syndrome and Cancer" in the Nov. 11, 1939, issue gives an erroneous impression regarding the authors of the syndrome.

In collaboration with Drs. William A. Swalm and Chevalier L. Jackson I have pointed out (Syndrome of Hypochromic Anemia, Achlorhydria and Atrophic Gastritis, THE JOURNAL, July 10, 1937, p. 108) and Correlation of Clinical and Gastroscopic Findings in Chronic Gastritis (Rev. Gastroenterol. 3:19, 1936) that Patterson and Kelly previously described this syndrome. I referred to the fact that D. R. Patterson (Brit. J. Laryng., Rhin. & Otol. 34:285 [Aug.] 1919) and A. B. Kelly (ibid., p. 289) had separately analyzed and presented a detailed group study from their respective clinics.

I feel that it is only fair to credit the priority of Patterson and Kelly's work, since the "Patterson-Kelly" syndrome was described three years prior to that of Plummer and Vinson.

In our article in THE JOURNAL just cited we reviewed, as was done in your editorial, the possibility of cancerous development in this group, but in the course of from four to five years of observation this has not occurred in our series. Of course appropriate therapy may have been prophylactic. Time and further experience will tell.

LESTER M. MORRISON, M.D., Philadelphia.

Queries and Minor Notes

THE ANSWERS HERE PUBLISHED HAVE BEEN PREPARED BY COMPETENT AUTHORITIES. THEY DO NOT, HOWEVER, REPRESENT THE OPINIONS OF ANY OFFICIAL BODIES UNLESS SPECIFICALLY STATED IN THE REPLY. ANONYMOUS COMMUNICATIONS AND QUERIES ON POSTAL CARDS WILL NOT BE NOTICED. EVERY LETTER MUST CONTAIN THE WRITER'S NAME AND ADDRESS, BUT THESE WILL BE OMITTED ON REQUEST.

JACKETS AND EXTERNAL APPLICATIONS IN PNEUMONIA

To the Editor:—In seeing cases of pneumonia in consultation, it seems to be the rule to find the patient within a heavy cotton jacket and heavily smeared with camphorated oil or some mentholated product and not intermittently with "antiphlogistine." I should like to ask whether there is any scientific proof that any external applications are of definite value in pneumonia or even in pleurisy. If of value, is the value in pain relieving or in producing resolution of the pathologic process? I leave the psychic value of this out of the question. Is there any justification in continuing the use of the cotton jacket, so-called pneumonic jacket? On the other hand, are they not actually harmful if not uncomfortable to the patient?

M.D., Washington.

ANSWER.—Reliable and cautious physicians observe relief of pain in pneumonias after counterirritation applied in a number of different ways. Aside from relieving pain there is no scientific proof that any external applications are of definite value in pneumonia or pleurisy. Embrocations, counterirritation, external applications and "antiphlogistine" (cataplasm of kaolin) have no effect on resolution. Resolution reflects an immunologic process, and the immunity mechanism is unaffected by counterirritation. Ever since emphasis has been placed on the etiology and specific therapy of pneumonias, many of the older therapeutic procedures have lost significance. The use of the so-called pneumonia jacket has become passé; it serves no useful purpose and has been discarded in many large services where pneumonia is given special attention and where excellent low mortality rates are obtained without it. Pneumonia jackets and counterirritants are harmful if they incorrectly place therapeutic emphasis so that the physician loses sight of the immunity problem involved. They may be uncomfortable, are heavy for prostrated patients to lift and may interfere with physical examinations, and when they are removed the patient may become chilled. They may interfere with necessary loss of heat, preventing evaporation, the chief cooling process, so that the fever is increased.

UNUSUAL NEUROLOGIC SYMPTOM FROM PNEUMONIA

To the Editor:—A well developed boy of 12 contracted pneumonia of the right lower lobe two months ago. Examination of the sputum revealed the influenza bacillus, the streptococcus and the pneumococcus (which could not be typed). There were 8,500 white blood cells with about 85 per cent polymorphonuclear leukocytes. The temperature ranged from 104 to 105 F. About the second day of his illness the patient complained of pain in the left forearm and also of inability to flex the terminal phalanx of the left thumb. He was given sulfapyridine on the fifth day and his fever promptly subsided, although the role redux continued for about three weeks. During his convalescence he complained of pain in the left arm and in both feet. He was able to walk only with difficulty. There was, however, no swelling at any time. The boy now has completely recovered, no longer has any pain and is attending school. However, the use of his left thumb has not returned. I have had him examined by a neurologist but nothing has been found. What did the boy have, and what can I do to restore the function of his thumb?

M.D., New York.

ANSWER.—The data concerning the pneumonia do not permit an etiologic diagnosis to be made but suggest the atypical form of pneumonia, not bacterial in origin, which was prevalent during the last year or two. The normal leukocyte count and the evidence of delayed resolution are characteristic of this disease. Its course was not influenced by sulfapyridine, and in the case described the subsidence of the fever may have been spontaneous, since the average course of this pneumonia lasted from four to five days.

Whatever kind of pneumonia the patient had, the complicating neurologic symptoms described are most unusual. The absence of swelling and of continued fever rules out multiple focal purulent arthritis. The symptoms were perhaps caused by multiple peripheral neuritis in spite of the fact that no other abnormal neurologic signs were found. In this event it is highly probable that the function of the thumb will gradually return to normal if, on electrical examination, no reaction of degeneration of the median nerve is found. Restoration may be hastened by massage, heat, exercise and stimulation with a faradic current.

EPINEPHRINE AND ELECTRIC SHOCK

To the Editor:—Is there any literature on contraindications to the use of epinephrine in the treatment of electric shock?

T. J. Cush, M.D., Johnstown, Pa.

ANSWER.—According to D. R. Hooker (*Am. J. Physiol.* 91:305 [Dec.] 1929) ventricular fibrillation is the common cause of death in electric shock; this is especially so in the low voltage shock from ordinary house currents. Epinephrine may also induce fatal ventricular fibrillation in conditions in which the heart is hyperirritable from the effects of poisons (benzene, chloroform). H. E. Hoff and L. H. Nahum (*J. Pharmacol. & Exper. Therap.* 52:235 [Nov.] 1934; *Am. J. Physiol.* 110:675 [Jan.] 1935) used acetyl-beta-methylcholine chloride for the prevention of ventricular fibrillation by electric shock and found that epinephrine counteracted the effect of the acetyl-beta-methylcholine chloride or in larger doses increased the possibility of fatal ventricular fibrillation. They also mentioned a case in which a man apparently recovered from the effects of a shock and then died when he got up to walk away. They suggested that this was due to the effect of an increased secretion of epinephrine on the heart. Hooker studied the effect of epinephrine on the isolated cat heart and found that it was ineffective in stopping fibrillation but that after the fibrillation had been stopped by other means epinephrine was of use in increasing the strength of contraction of the heart muscle.

While there has been no specific study of the effect of epinephrine on a heart stopped by an electric shock comparable to that causing heart failure in man, most experiments seem to contraindicate its use.

RECURRENT DISLOCATIONS OF SHOULDER

To the Editor:—A girl aged 20 who is in good health has had repeated anterior dislocations of the right humerus. The dislocations are easily reduced under light anesthesia. After the first accident her arm and shoulder were in a plaster cast for six weeks, but there have been four dislocations since. After each accident she wears her arm in a sling for about two weeks and then she considers herself recovered until the next time. She refuses surgical treatment and is anxious to know if there is any device she could wear that would act as a preventive against further dislocations. Any suggestions would be appreciated.

Herbert J. Schwartz, M.D., Chollis, Ida.

ANSWER.—Recurrent dislocations of the shoulders are most satisfactory treated by one of two or three operative procedures, probably the most successful being that described by Nicola. No mechanical device which permits reasonable use of the arm can be entirely successful in preventing these dislocations. The most effective consists of a cuff about the arm at the level of the middle third of the humerus and a band or belt about the thorax just below the breasts. A light chain such as that worn on watches may then be attached to the band on the arm and, through a series of buttonhole openings in the clothing; to the chest strap in the axillary line. This chain should be just long enough to permit abduction of the elbow from the side for a distance of 8 inches, and forward flexion is then automatically limited.

This type of device has been reasonably successful, even when worn by football players, but it is more difficult to prevent redislocation of the true anterior type than if the weak spot in the capsule were more definitely inferiorly placed.

PREMENSTRUAL ASTHMA AND ENDOCRINES

To the Editor:—In *The Journal*, Oct. 21, 1939, page 1586, there is the statement, in answer to Dr. R. E. Show's query, "Every one agrees that many female asthmatic patients are worse just before the flow and feel better as soon as menstruation begins. Because of this, many physicians give injections or tablets of ovarian material." I fail to see why ovarian material should be given in such a case, since it is known that with the menstrual flow the estrogenic hormone in the blood diminishes abruptly. If at this point the asthmatic attacks improve, why should one inject estrogenic substance to stimulate the premenstrual state? This would be most illogical; as a matter of fact such injections are as a rule accompanied by aggravation of the asthma unless it has no relationship to the ovarian status.

William Wolf, M.D., New York.

ANSWER (This was referred to the consultant on whose answer Dr. Wolf comments).—From clinical experience there is no doubt at all that a good many female asthmatic patients in whom asthma is intensified before menstruation have been benefited by the administration of estrogenic preparations. There are also reports of good results from corpus luteum. It is difficult to defend this result from the theoretical point of view, but many who see considerable numbers of asthmatic patients will testify to the fact that after taking the ovarian extract the patients are able to go through subsequent menstruations with little or no asthma.

POSSIBLE CALCIFIED TUMOR OF CHOROID PLEXUS

To the Editor:—I should like information regarding the treatment for an enlarged and calcified choroid plexus of the left lateral ventricle in a woman aged 54. The diagnosis was made by a ventriculogram. This woman complains of excruciating pain in the left side of the head at frequent intervals, absolute insomnia and occasional spells of dizziness; she sees spangled lights at times and has double vision in the lateral gaze. The latter has been explained as a third and fourth nerve vascular lesion. The eyegrounds are normal with the exception of some mild sclerosis. The eye fields are normal. Blood count shows 14,000 white cells and 4,500,000 red cells. Differential count and blood smears are normal. There is no nausea, but there have been frequent periods of vomiting; this has not been characteristically projectile, but the food would well up into her mouth much like a regurgitation without warning. X-ray study of the gastrointestinal tract and gallbladder yields negative results. The urine is normal. The Wassermann reaction of the blood is negative. The electrocardiogram is normal. The basal metabolic rate is -22 per cent. The pulse is regular and within normal limits. The temperature is normal. The blood pressure is now 120 systolic and 70 diastolic but has been down to 104/64, and the patient has shown signs of orthostatic hypotension. There are no focal signs, but the woman has had spells characterized by generalized numbness of the body, flushing of the face, lasting only a few seconds, and incognizance of her environment, followed by precordial palpitation and diarrhea. Results of further neurologic examination are negative. Are there any similar cases reported? Can you refer me to the literature? How would you explain the leukocytosis? Can it be dehydration? What would be the procedure of treatment?

M.D., New York.

ANSWER.—It is only occasionally that calcified tumors of the choroid plexus cause trouble. Without seeing the ventriculograms, which of course are all important in diagnosis, one would feel that the burden of proof was on the diagnosis as stated. However, it is entirely possible. The history suggests a brain tumor near the midbrain or third ventricle. No explanation of the leukocytosis is apparent; it may or may not be relevant but is not due to dehydration. A series of tumors in this region was reported by W. E. Dandy (Benign, Encapsulated Tumors in the Lateral Ventricles of the Brain, Baltimore, Williams & Wilkins Company, 1934). The treatment is removal of the tumor, the exact localization of which can be made by ventriculography.

DAIRY PRODUCTS AFTER MEAT

To the Editor:—The Hebrew dietary laws, as prescribed in the Talmud, prohibit the ingestion of milk or other dairy products for at least six hours after eating meat; nor may meat be eaten together with milk. No reason or explanation is given for such an edict. It is assumed, however, by some authorities that such a prohibitive regulation was formulated as a purely sanitary and hygienic measure against certain gastrointestinal disturbances which might result from such a combination of foods when consumed in tropical climates. I shall appreciate information as to whether any research or experimental work has been done by scientific medicine along these lines and what the opinion of medical authorities is relative to the meat-milk problem.

M.D., Connecticut.

ANSWER.—There is no meat-milk problem although good sanitation and hygiene must be observed in the preparation and handling of meat and milk and, indeed, all foods. It is likely that early Hebrew dietary laws were formulated as sanitary measures, and a fairly complete discussion of this interesting topic is available in the following articles:

- Jewish Ceremonials and Food Customs, *J. Am. Dietet. A.* 4:91 (Sept.) 1928.
Jewish Contributions to the Hygiene of the Digestive Tract, *M. J. & Rec.* 125:49 (Jan.) 1927.
Jewish Dietary and Hygienic Laws, *Pub. Health J.* 14:483 (Nov.) 1923.
Jewish Food Habits, *J. Am. Dietet. A.* 9:389 (Jan.) 1934.
Historical and Biological Evolution of the Human Diet, *Am. J. Digest. Dis.* 1:215 (May) 1934.

MAXILLARY SINUSITIS IN PREGNANCY

To the Editor:—A patient six months pregnant has had an acute attack of chronic maxillary sinusitis. Her face swells unilaterally, with slight pain. Constricting drugs on the mucous membrane evidently open the passage but little, if any, discharge results. Every few days she complains of a sore throat, which is injected on inspection. The problem is the choice of some type of vaccine, either stock or autogenous (which kept her free from attacks for about eighteen months), roentgen therapy or ultrashort wave diathermy. Are any of these procedures contraindicated in pregnancy?

M.D., New York.

ANSWER.—The history as given assumes that there has been nothing left undone to establish a diagnosis. Unilateral swelling of the face, while it may occur, is not common in maxillary sinusitis and it would require careful study and x-ray examination to make sure that there is no cyst or new growth present. The fact that constricting drugs do not shrink the mucous membrane should impel the examining physician to make sure by history, nasal smears, and other measures that there is no concomitant allergic condition present.

As to the choice of treatment, any one of the treatments mentioned can be used or all three of them without affecting the pregnant state. When these treatments are instituted, the physician should know that he uses them empirically and that while none of them are curative, or uniformly successful, palliation of symptoms is also a concern of the doctor and provides the justification for such treatment.

LACTATION AND MENSTRUATION

To the Editor:—Does menstruation in a nursing mother effect the baby? If so, in what ways?

L. A. Crowell, Jr., M.D., Lincoln, N. C.

ANSWER.—The breast milk of a nursing mother is said to be qualitatively unaltered during this period. Occasionally there is a lessened supply of breast milk during the menses, and the reaction on the baby may be one of hunger. The emotional factor and increased nervous tension which accompany the menstrual period in some women may be the cause of this diminution in quantity.

In the Middle Ages it was common practice to nurse the child until the first deciduous dentition was completed. Among many primitive races nursing at the breast is common until the child is of a considerable age. No difficulty arises from menstruation on the part of the mother. It is apparent therefore that menstruation per se has no direct effect on the breast milk or the infant, and it has never been recommended as a contra-indication to nursing.

PNEUMOCOCCIC ARTHRITIS OF HIP

To the Editor:—Kindly send me information regarding frequency, prognosis and treatment of pneumococcal infection of the hip following labor pneumonia. I am especially interested to know the proper treatment in these cases.

Hilmer R. Schmidt, M.D., Petersburg, Va.

ANSWER.—Pneumococcal infections of the hip are rare, although a definite percentage incidence cannot be given. In one series of 1,800 cases of pneumonia, pneumococcal arthritis was observed as a complication in only two cases. The disease usually occurs in children, although it may occur in adults. Treatment in the past has been essentially conservative, aspiration being performed repeatedly if necessary and drainage instituted only when the condition seems to be getting out of control. In addition, the surgeon now has the advantage of the use of sulfanilamide and the drugs of that group, which have proved so successful in the treatment of pneumonia. Therefore it would seem best in the light of this knowledge to adhere even more closely to surgical conservative measures.

INHERITANCE OF LOOSE JOINTS

To the Editor:—Can you give me information with regard to the hereditary tendency and pathology of abnormally loose joints?

George C. Olds, M.D., Paulina, Iowa.

ANSWER.—Congenital relaxation of joints, produced by over-long ligaments and other capsular structures permitting abnormal ranges of motion, appear to be simple recessive hereditary characteristics. In the recessive patterns the appearance of mild abnormal conditions, such as the one referred to, is not likely to be inherited by the children unless the marriage is between cousins.

MALINER'S TEST

To the Editor:—In the December 9, 1939 issue of The Journal on page 2171, M.D., Illinois, asks for information regarding Maliner's test. The reply unfortunately, to my belief, was misleading, and I wish to correct it. The article by W. F. Matthews and myself in the Archives of Pediatrics 56:142 (March) 1939 was merely a corroboration of work done by Master with a few modifications. This test has never to my knowledge been personalized. However, the term "Maliner's test" has frequently been attached to work done by me on the use of epinephrine 1:1,000 as a means of accentuating organic precordial murmurs. This was first reported in the Archives of Pediatrics 49:305 (May) 1932 and later by Maliner and Okin in the Journal of Pediatrics 10:77 (Jan.) 1937.

Martin M. Maliner, M.D., Brooklyn.

VISUAL DISTURBANCES AND SULFANILAMIDE

To the Editor:—With regard to the query of Dr. Manfred Landsberg in The Journal, Dec. 16, 1939, page 2260, I have seen a patient whose refraction became 6 diopters more myopic following a small dose of sulfanilamide. There was almost total obliteration of the anterior chamber of both eyes. I was unable to determine whether this was due to swelling or forward displacement of the lenses because in my fear that a glaucoma might develop I had used physostigmine to constrict the pupil. In three days the eyes had returned to normal.

Ray W. Hughes, M.D., Detroit.

Medical Examinations and Licensure

COMING EXAMINATIONS

STATE AND TERRITORIAL BOARDS

Examinations of state and territorial boards were published in THE JOURNAL, February 3, page 433.

NATIONAL BOARD OF MEDICAL EXAMINERS

NATIONAL BOARD OF MEDICAL EXAMINERS: Parts I and II, Feb. 12-14; Part III, June or July, to be given in medical centers having five or more candidates desiring to take the examination. Exec. Sec., Mr. Everett S. Elwood, 225 S. 15th St., Philadelphia.

SPECIAL BOARDS

AMERICAN BOARD OF ANESTHESIOLOGY: An Affiliate of the American Board of Surgery. Oral. Part II. New York, June 10-11. Applications must be received 60 days prior to examination. Sec., Dr. Paul M. Wood, 745 Fifth Ave., New York.

AMERICAN BOARD OF DERMATOLOGY AND SYPHILOLOGY: November 1940. If a sufficient number of applications are received before March 1 there will be an examination at New York, June 10-14. Sec., Dr. C. Guy Lane, 416 Marlboro St., Boston.

AMERICAN BOARD OF OBSTETRICS AND GYNECOLOGY: General oral and pathologic examinations (Part II) for all candidates (Groups A and B) will be conducted in Atlantic City, N. J., June 7-10. Applications for admission to Group A, Part II, examinations must be on file not later than March 15. Sec., Dr. Paul Titus, 1015 Highland Bldg., Pittsburgh (6).

AMERICAN BOARD OF OPHTHALMOLOGY: Oral. New York, June 8-10; Cleveland, Oct. 5. Sec., Dr. John Green, 6830 Waterman Ave., St. Louis.

AMERICAN BOARD OF OTOLARYNGOLOGY: New York, June 3-5. Sec., Dr. W. P. Wherry, 1500 Medical Arts Bldg., Omaha.

AMERICAN BOARD OF PATHOLOGY: New York, June 10-11. Sec., Dr. F. W. Hartman, Henry Ford Hospital, Detroit.

AMERICAN BOARD OF PEDIATRICS: Kansas City, Mo., May 18, following the Region III meeting of the American Academy of Pediatrics. Seattle, June 2. Sec., Dr. C. A. Aldrich, 723 Elm St., Winnetka, Ill.

AMERICAN BOARD OF PSYCHIATRY AND NEUROLOGY: Cincinnati, May 17-18. Sec., Dr. Walter Freeman, 1028 Connecticut Ave. N.W., Washington, D. C.

AMERICAN BOARD OF RADIOLOGY: New York, June 7-10. Sec., Dr. Byrl R. Kirklin, 102-110 Second Ave., Rochester, Minn.

Texas November Examination

Dr. T. J. Crowe, secretary, Texas State Board of Medical Examiners, reports the written examination held at Austin, Nov. 20-22, 1939. The examination covered twelve subjects and included 120 questions. Eighteen candidates were examined, fourteen of whom passed and four failed. Fifty-four physicians were licensed by reciprocity. The following schools were represented:

School	PASSED	Year Grad.	Per Cent
University of Colorado School of Medicine.....	(1934)		86.5
Harvard Medical School.....	(1939)		84.8
University of Michigan Medical School.....	(1935)		83.4
Meharry Medical College.....	(1937)		76
Medizinische Fakultät der Universität Wien.....	(1925)		79.8
Christian-Albrechts-Universität Medizinische Fakultät, Kiel.....	(1931)		78.2
Hamburgisch-Schlesische-Fakultät, Breslau.....	(1936)		77.8
Vereinigten-Friedrichs-Universität Medizinische Fakultät, Halle-Wittenberg.....	(1926)		75
Regia Università degli Studi di Bologna, Facoltà di Medicina e Chirurgia.....	(1937)		79.5
Osteopaths *.....	75.7, 78.6, 79.2,		83.3
School	FAILED	Year Grad.	Per Cent
Japan Medical College, Hongo.....	(1910)		64.5
Universidad Nacional Facultad de Medicina, México.....	(1928)		72.5,
Osteopath *.....			70

School	LICENSED BY RECIPROCITY	Year Grad.	Reciprocity with
College of Physicians & Surgeons, Little Rock.....	(1911)		Arkansas
University of Arkansas School of Medicine.....	(1937)		Arkansas

University of Bristol Faculty of Medicine.....	(1934)			New Jersey

* Examined in medicine and surgery.

Georgia October Examination

Mr. R. C. Coleman, secretary, Georgia State Board of Medical Examiners, reports the written examination held at Atlanta, Oct. 10-11, 1939. The examination covered ten subjects and included 100 questions. An average of 80 per cent was required to pass. Twelve candidates were examined, all of whom passed. Eleven physicians were licensed by reciprocity and five physicians were licensed by endorsement. The following schools were represented:

School	PASSED	Year Grad.	Per Cent
College of Medical Sciences.....	" "	" "	83.2, 86.2
Emory University School of Medicine.....	" "	(1939)	84.1
University of Georgia.....	" "	(1939)	83.8
The School of Medicine of the Division of Biological Sciences.....		(1936)	82.6
Tulane University of Louisiana School of Medicine.....		(1939)	81.1,
81.6, 86.4, 91.6			
Harvard Medical School.....		(1938)	86.7
Creighton University School of Medicine.....		(1936)	81.7

School	LICENSED BY RECIPROCITY	Year Grad.	Reciprocity with

University of Pennsylvania School of Medicine.....	(1933)		N. B. M. Ex.

* These applicants completed four years' medical work and will receive an M.D. degree on completion of internship.

Arkansas November Examination

Dr. D. L. Owens, secretary, State Medical Board of the Arkansas Medical Society, reports the written examination held at Little Rock, Nov. 9-10, 1939. The examination covered twelve subjects. An average of 75 per cent was required to pass. Two candidates were examined, all of whom passed. The following schools were represented:

School	PASSED	Year Grad.	Per Cent
University of Arkansas School of Medicine.....	(1939)		87.1
The School of Medicine of the Division of Biological Sciences.....	(1939)		90

Seven physicians were licensed by reciprocity and one physician was licensed by endorsement from July 25 through December 26. The following schools were represented:

School	LICENSED BY RECIPROCITY	Year Grad.	Reciprocity with
University of Arkansas School of Medicine.....	(1930)		Mississippi
University of Georgia Medical Department.....	(1924)		New York
State University of Iowa College of Medicine.....	(1933), (1936)		Iowa

Book Notices

Sterility and Impaired Fertility: Pathogenesis, Diagnosis and Treatment. By Cedric Lane-Roberts, M.S., F.R.C.S., F.R.C.O.G., Gynecological Surgeon, Royal Northern Hospital, London, Albert Sharman, M.D., M.R.C.O.G., Assistant Surgeon, Royal Samaritan Hospital for Women, Glasgow, Kenneth Walker, F.R.C.S., Surgeon to the Genito-Urinary Department, Royal Northern Hospital, London, and B. P. Wiesner, D.Sc., Ph.D., F.R.S.E., Consulting Biologist, Royal Northern Hospital, London. With a foreword by The Rt. Hon. Lord Horder, G.C.V.O., M.D., F.R.C.P. Cloth. Price, \$5.50. Pp. 419, with 90 illustrations. New York: Paul B. Hoeber, Inc., 1930.

The field of sterility has become so extensive that it now requires a group of workers to deal adequately with all its various aspects. This condition is fulfilled in the present volume, which is the joint production of two gynecologists, a urologist and a biologist, each well known for his valuable contributions to the subject. Their book is complete and authoritative. It discusses thoroughly the modern views on the causation of infertility, with a critical analysis of the supporting evidence. Every recognized method of diagnosis and treatment receives attention. In some instances the weighting of these items does not accord with their practical importance; for example, while operations to remedy tubal occlusion are fully described, there is only the briefest mention of the surgical treatment of polycystic ovaries. The sections on endocrinology present an admirable summary of newer developments in that department of medicine, including not only theory but also practical application to problems of reproductive failure. The technique and interpretation of both endometrial and testicular biopsies are clearly explained. A good half of the total subject matter concerns itself with the male partner; in this is included a consideration of his responsibility in cases of habitual miscarriage. Throughout the book the authors maintain a commendable attitude of caution in their conclusions and of conservatism in their recommendations. The numerous illustrations are well chosen and beautifully executed. A series of appendixes dealing chiefly with technical laboratory procedures, a sufficient bibliography and a good working index complete the volume. The main feature of this book is its wealth of scientific detail, and one is led to wonder whether that very virtue may not overwhelm the ordinary practitioner who seeks primarily simple guidance in clinical procedure. The specialist, on the other hand, will welcome a treatise which is the last word to date on normal and abnormal human reproductive physiology.

Symposium on the Synapse. By Herbert S. Gasser and others. Reprinted from *Journal of Neurophysiology*, 1930, 2. Paper. Price, \$1.50. Pp. 361-474, with 25 illustrations. Springfield, Illinois & Baltimore: Charles C. Thomas, Publisher, 1930.

This classic of neurophysiology represents the present conceptions of synaptic conduction. It is invaluable and should be carefully studied. Gasser considers the axon as a sample of nervous tissue and qualitatively, therefore, as casting light on the physiology of synapse. This is achieved through the experimental demonstration of subnormal excitability in the axon as well as other parts of the neuron following single spikes or trains of spikes. This phenomenon renders the later discussion of inhibition and facilitation more understandable.

Erlanger then considers the question of differences between nerve fiber and synapse conduction. With the aid of information obtained by stimulation and polarization of the axon and studying such phenomena as latency, one way transmission, repetition, temporal summation, facilitation, and transmission of the action potential across a nonconducting gap, he is able to demonstrate "a temporal relation between subthreshold effect of a shock applied to a fiber, the subthreshold effect of an action potential beyond a block at a node and the subthreshold effect of an action potential blocked at a neuromuscular junction by curare." On the evidence presented he feels that transmission of the impulse across a synapse depends entirely on the influence exerted by the potential difference on the excitability and does not depend on substances released at the nerve ending.

Bronk passes from analogous behavior studies of axons to the study of sympathetic ganglions as samples of synaptic mechanisms. He attempts to correlate the electrical characteristics with the interesting excitatory effects of acetylcholine and potassium ions on the postganglionic fibers of sympathetic ganglions.

While it is not desired to make a definite statement on the basis of available evidence, a definite scheme favors the dualistic theory of excitation at the synapse. His primary thesis, based on both the electrical and the chemical evidence, is that of a dynamic synapse undergoing a continuous change of state modified by numerous factors.

De No, by virtue of a detailed and ingenious study of the internuncial neurons lying between sensory nerves and motor nuclei of the medulla, and also by the method of electrical stimulation and pick-up and by a modification of the experiments of Wedensky, tends to an essentially electrical interpretation of conduction at the synapse. He says that "the action currents of nerve impulses arriving at the synapses may prove not to be the agents for synaptic transmission but everything happens as if they were." The cocaine nerve block experiment of Wedensky is enlarged, studied in detail and set up as a model of synaptic transmission with possibilities as fascinating as those of the iron wire model of Lillie.

Forbes completes the monograph with a summary of the more recent developments of the humoral aspect of synaptic transmission and emphasizes the great number of unanswered questions about the relative importance of each of the factors demonstrably concerned in the physiology of the synapse. Chemical versus electrical excitation at the synapse is still not a solved problem.

L'électro-encéphalogramme, normal et pathologique. Par Ivan Bertrand, directeur à l'Ecole des hautes études, Jean Delay, médecin des hôpitaux de Paris, et Jacqueline Guillemin, assistante à l'Institut de neurobiologie. Paper. Price, 50 francs. Pp. 293, with 94 illustrations. Paris: Masson & Cie, 1930.

In this first monograph on the electro-encephalogram an attempt is made to cover all aspects of the clinical phases of the subject. A historical chapter includes the demonstration of electric currents in animal brains by Caton in 1875 as well as the subsequent contributions made in Germany, England and America, the literature being briefly reviewed. This is followed by a technical discussion of the principles of amplification and recording adapted at once to the purposes of the biologist setting up a laboratory and to those of the general reader.

The physical character of the alpha rhythm is discussed, brief attention being paid to its origin as argued by Adrian and by Berger. The physical characteristics of the beta rhythm, less well known, are given corresponding cursory treatment. Mention of delta waves completes the formal description. The phylogenetic differences in rhythms, the development of the regular ten per second adult rhythm from the slow irregular patterns of infancy, individual differences, modes of classification and criteria of "normal" are completely represented.

Normal and pathologic types of sensory activity are presented in visual, auditory, cutaneous, gustatory, olfactory and proprioceptive studies of the animal brain. The studies of the effects of visual, auditory and tactile stimuli on the alpha rhythm of man, while completely represented, indicate the infancy of this phase of the subject. Pathologic conditions such as hemianopia, hallucinations induced by mescaline and hypnosis, and finally a differential test for hysterical anesthetics are presented.

Included under considerations of normal and pathologic psychic activity as represented in the electro-encephalogram is a discussion of the accepted "stages of normal sleep." The differential effect of the anesthetic gases and barbiturate sedation on the cortical rhythm during the induction of sleep is striking in that the barbiturates induce a more "normal" type of sleep waves. Comas and torpors of various sorts are attended by slow delta waves. Narcolepsy and prolonged hypnosis are attended, on the other hand, by diminution of the alpha rhythm. That the phenomena appearing in sleep may be duplicated by cortical differentiation is demonstrated by Bremer's experiments with the "isolated brain" technic.

Psychiatric considerations concern mental retardation, wherein only idiocy is characterized by slow irregular patterns while imbecility and mental defect have more nearly normal patterns. Myxedema and dementia paralytica are given detailed description, and finally the inconstant features of schizophrenia and their modification by insulin and metrazol therapy in the direction of enhancing the usually weak alpha rhythm are discussed.

Normal and pathologic motor activity include correlations of frequency of finger tremor and precentral rhythms and differentiation of occipital and precentral alphas. Some consideration is given to the rapid cerebellar rhythm and to cerebellocerebral relationships. The well established patterns of grand and petit mal and the current American concept of epilepsy as a paroxysmal cerebral dysrhythmia are well presented. The inconstant features of parkinsonism are less well known and are presented as an open problem.

Included in the section on localizing the value of the electroencephalogram is a discussion of correlations of precentral betas and occipital alphas with their respective sensory representations in cutaneous and visual spheres. The sharp correlation of electrical fields with cyto-architectonic ones in the animal and the more diffuse nature of this phenomenon in man are shown. Instruction in the use of the instrument for localization of cortical lesions such as tumors is amply given by the use of case material.

Two final chapters on experimental alteration of the cortical rhythms by ischemia, asphyxia, chemicals, pH change differentiation by the Bremer technic and considerations of the general question of neuronal automatism and synchrony conclude this readable summary of the subject of clinical electro-encephalography.

Treatment of Some Common Diseases (Medical and Surgical). By Various Authors. Edited by T. Rowland Hill, M.D., M.R.C.P., Physician to the Southend General Hospital, London. Cloth. Price, \$5. Pp. 398, with 90 illustrations. Baltimore: William Wood & Company, 1939.

The twenty-one authors of this book are not perhaps among those British practitioners whose names are best known in American medical circles nor is the Southend General Hospital of which they are staff members particularly famed on our side of the Atlantic; it is therefore quite enjoyable to welcome from this group and hospital a pleasing little book. The twenty-six subjects covered seem, to be sure, to have been chosen quite at random, as though each man had simply elected to write on a topic in which he was much interested, but the style is on the whole quite pleasing and the book certainly fulfils the editor's wish that it be looked on merely as a small volume to be taken down and read from time to time by practitioner and student.

The subjects included are angina pectoris, heart failure, pleurisy, bronchopulmonary suppuration, anemia, cerebral vascular disease, digestive disorders of infancy and childhood, prophylactic treatment by active immunization, malignant disease of the pharynx, obstructive jaundice due to malignant disease, hemorrhage from the intestinal tract, enlargement of the prostate gland, infections of the face and neck, suppurative lesions about the knee joint, head injury and its complications, uterine hemorrhage, delay in labor, shock during anesthesia, preanesthetic medication, x-rays in the treatment of malignant disease, injuries to the skin and mucous membrane in radiation therapy, moles, warts and angiomas, ocular complications of some common disorders of the skin, earache, dental caries and postoperative wound complications. There are numerous good photographic reproductions both of x-ray films and of facies, a number of line drawings and charts, and several color plates. The index seems adequate but there is no bibliography, which is perhaps not a serious omission in this type of book.

Eye, Ear, Nose and Throat Manual for Nurses. By Roy H. Parkinson, M.D., F.A.C.S., Head Oculist and Aurist to St. Joseph's Hospital, San Francisco, California. Fourth edition. Cloth. Price, \$2.25. Pp. 243, with 79 illustrations. St. Louis: C. V. Mosby Company, 1939.

In a competent fashion the author discusses the anatomy of the eye, ear, nose and throat. He devotes a great deal of attention to the common diseases of these regions. At the end of the various chapters are questions relating to the material covered. The proper knowledge of the answers presumably would mean that the student nurse had a good understanding of the various details discussed in the text. There follows then the discussion of the care and treatment of eye, ear, nose and throat conditions and finally the technic of assisting the surgeon in these regions. This part is particularly valuable. Reproductions of photographs show the instruments which are used, which should be of great value to supervisors and senior nurses as well as informative for the younger group. In the hands of those who devote time to the teaching of nurses a manual of this character should be of great value.

Klinische Chemie und Mikroskopie: Ausgewählte Untersuchungsmethoden für das medizinisch-chemische Laboratorium. Von Dr. Lohar Hallmann, Direktor der biochemischen und bakteriologischen Abteilung des städtischen Kaiser-Friedrich- und Kaiserin-Friedrich-Kinderkrankenhauses in Berlin. Paper. Price, 12 marks. Pp. 387, with 113 illustrations. Leipzig: Georg Thieme, 1939.

This is an excellent little book on clinical chemistry and microscopy. It is divided into three parts: general laboratory technics, qualitative, physical and general investigations, and quantitative micro methods. Introductory remarks relate to the handling of glassware, weighing, making the solutions, reagents and bacterial stains. This part is well done. The first chapter deals with investigation of sputum, stomach contents and duodenal juices. The second chapter relates to general investigations of intestinal contents, chemical and microscopic. There are fifteen pages on parasites and protozoa. The third chapter deals with details of sputum analysis. The fourth chapter discusses exudates, transudates and cyst fluids. This is only two and a half pages and necessarily is exceedingly brief. The fifth chapter relates to investigations of urine and covers ninety-one pages. It is abreast of the time but rather superficial. The sixth chapter discusses spinal fluid, sixteen pages in all. It gives details of the Heller, Weichbrodt, Nonne-Apelt, Pawlowsch, Pandey and Lange tests, the mastie reaction, the normomastic reaction of Kafka, the lumbotest of Emanuel, a quantitative albumin test of Kafka, the Takata-Ara reaction, the tryptophan reaction of Voisinot, the chemical test for sugar, the hemolysin test of Weil and Kafka and the vitamin C test. The method for counting cells is that utilizing the well known Fuchs-Rosenthal counting chamber and the Jessen counting chamber. The seventh chapter discusses blood; this consists of 187 pages and is a good chapter. The eighth chapter discusses quantitative chemical investigations of body fluids, which are mostly micro methods. This is a valuable brief or outline of clinical chemical procedures. To use a continental expression, it is a good *vade mecum*. There is an excellent table of medicochemical terms and a table devoted to the appearances in various diseases. So far as references to the literature are concerned, there is a table of references to the literature of blood chemistry covering six printed pages. It is noteworthy that among these references there are but twenty references to American articles, which is a typical German method of ignoring our literature.

British Health Resorts, Spa, Seaside, Inland, including Those of the British Dominions and Colonies. With Chapters on the Science of Waters and Baths, the Climates of the Coast and the "Invalids' Winter." Edited for the Association by R. Portescue Fox, M.D., F.R.C.P., F.R.Met.S. Assisted by Wyndham E. B. Lloyd, M.R.C.S., L.R.C.P., D.P.H. With a foreword by the Rt. Hon. Walter Elliot, Minister of Health. Official Handbook of the British Health Resorts Association. Paper. Price, 2s. 6d. Pp. 317, with illustrations. London: The Association, 1939.

In the foreword the minister of health stresses the importance of health resorts in the national fitness campaign. He points out that the recent extension of holidays with pay makes the health resorts of inestimable value. The chapters on the scientific basis of medical practice at the spas and the coast have been rewritten. Also the analysis of the regional climates has been amplified with new data. The editor has presented a simple classification of mineral waters and has agreeably omitted all claims for the specificity of any particular water for any particular condition. He points out the fact that the selection of the proper spa for treatment depends to a considerable degree on the constitution of the patient as well as on his particular disease. This emphasizes again the important fact that spa therapy is effective through its influence on disordered bodily function rather than being a specific for the disease. In the report of the medical advisory committee, the concise and clearly stated work and place of spas in promoting and maintaining health and preventing disease is emphasized. The ministry of health is urged to act in this field by inspection and recognition of the spas. The section on spas provides condensed information for the physician which has been approved by the medical advisory committee of the association regarding location, climate, the waters, the treatments, the indications and entertainment features. A notable omission is information regarding the physicians in practice at each spa. Information regarding living accommodations is provided in a separate section made up of the advertisements of the various hotels. The importance of studying the factors of climate such as pressure, temperature, wind, light, humidity, sunshine, precipitation and electricity as

they influence or produce the bracing tonic or relaxing sedative climate is clearly emphasized. The section of seaside resorts of the British Isles lists information regarding their location, climate, sea bathing, indications and attractions. Their hotels are listed in the special section.

Obstetrical Manikin Practice. By Lyle G. McNeile, M.D., Professor of Obstetrics and Gynecology, University of Southern California School of Medicine, Los Angeles. Cloth. Price, \$2. Pp. 111, with 38 illustrations. Baltimore: William Wood & Company, 1939.

This little manual is well done and serves to replace the use of the larger textbooks in the manikin classroom. The book amounts to an outline of operative obstetrics and as such should prove valuable to the student, advanced or beginning. The only objection that can be raised to this volume is that it can be considered inadequately illustrated. Such a book has long been needed as an addition to the American literature, and McNeile has made an excellent beginning. No doubt the needed revisions will be made in future editions. This book can be recommended to the serious student of obstetrics.

Bureau of Legal Medicine and Legislation

MEDICOLEGAL ABSTRACTS

Copyright: Excerpt from Medical Book Used for Commercial Purposes.—One of the plaintiffs, referred to by the court as the "use-plaintiff," was the author of a book on the human voice which was copyrighted by the publishers. After the publication of the book, the defendant tobacco company published and widely circulated a pamphlet entitled "Some Facts About Cigarettes," in which under the heading "Do cigarettes affect the throat?" appeared quotations attributed to the author and which in fact were copied, although not exactly, from matter appearing in the book on the human voice. The publishers of the book, "to the use of" the author, filed a complaint in the United States district court, eastern district, Pennsylvania, against the defendant tobacco company, charging copyright infringement.

The complaint averred that the use of the excerpt from the book in advertising matter of the nature under consideration cast reflections on the professional ethics of the author and brought down on him the term "commercialist," all of which contributed to negative and deter the sale of the book. The complaint further alleged that the defendant had realized large profits and advantages from the infringement and that it was prepared to continue the acts complained of, unless restrained. The defendant moved to dismiss the bill, urging that the copied matter was negligible in quantity, that its literary or scientific content was insignificant and that the copying did not exceed a fair use of a scientific treatise, due acknowledgment having been made to the author.

In order to constitute an infringement of the copyright of a book, said the court, it is not necessary that the whole or even a large portion of the book shall have been copied. Furthermore, the reproduction need not be literal and exact; it is piracy if it appears that the copyrighted work has been copied, although altered or paraphrased. The three sentences from the book that were used by the defendant, while constituting but a small part of the book, represented those portions of it which were pertinent to the subject of the defendant's pamphlet. Furthermore, the matter that was reproduced from the book constituted about one twentieth of the pamphlet. Under these circumstances, the court could not say that the matter used by the defendant was so unsubstantial as to afford no remedy.

The fact that the defendant acknowledged the source from which the matter was taken did not excuse the infringement. While the acknowledgment indicated that the company did not intend unfair competition, it did not relieve the defendant from legal liability for the infringement.

The infringement complained of was not excusable on the ground that the defendant was making no more than a fair use of the author's work. It is true that the law permits those working in a field of science or art to make use of ideas, opinions

or theories, and in certain cases even the exact words contained in a copyrighted book in that field. This is permitted in order "that the world may not be deprived of improvements, nor the progress of the arts be retarded." In such cases, the law implies the consent of the copyright owner to a fair use of his publication for the advancement of the science or art. This principle, however, had no application in this case. The pamphlet was a publication not in the field in which the author wrote, nor was it a scientific treatise or a work designed to advance human knowledge; it was intended to advance the sale of the defendant's product, a purely commercial purpose, and there arose no implication that the author consented to the use of his work for such a purpose.

Finally, the defendant urged that the action was improperly brought in the name of the publishers "to the use of" the author. In the opinion of the court, this point was well taken, for there is no such thing as "suing to the use" in equity. Here, the author of the book for whose benefit the publishers acquired a copyright was entitled to maintain the suit in equity in his own name. The improper joinder of the publishers as plaintiff was, however, the court said, amendable, and the plaintiffs were accorded leave to amend the bill by eliminating the publishers as a party plaintiff. Counsel for the plaintiffs also requested leave to amend the bill so as to introduce a cause of action arising out of the alleged violation of the author's right of privacy by the defendant's pamphlet. Without passing on the question whether or not such a right exists, the court found difficulty in understanding how the copying of a book which the author had published to the public could be held to be an invasion of his privacy. Such a right, however, the court pointed out, if it existed, involved an entirely new and essentially different cause of action based on an entirely different ground of jurisdiction. This new cause of action, the court said, could not be introduced into the present copyright action under the guise of an amendment to the complaint.

The court, therefore, refused the motion to dismiss the bill of complaint on condition that the bill be amended by eliminating the publishers as a party plaintiff.—*Henry Holt & Co., Inc., to Use of Felderman v. Liggett & Myers Tobacco Co. (Pa.), 23 F. Supp. 302.*

Workmen's Compensation Acts: Lead Poisoning as Accidental Injury.—The principle issue involved in this case was whether the death of the employee from lead poisoning resulted from accidental injuries received within the scope of his employment, and hence compensable under the workmen's compensation act of Texas, or whether the lead poisoning constituted an occupational disease for which no compensation was provided by the act. The district court granted compensation, after having charged the jury that an occupational disease is one acquired in the usual and ordinary course of an employment, which disease, from common experience, is recognized to be incidental thereto and is the usual and ordinary result incident to the pursuit of an occupation and must, in the nature of things, be the result of a slow and gradual development. The insurer appealed to the court of civil appeals of Texas, Galveston.

For more than five years prior to his death the employee had been employed by an iron and steel company where he was exposed to fumes and poisonous gases arising from melted lead. On May 15, 1936, the employee inhaled an unusually large quantity of poisonous lead fumes. On the morning of that day he appeared for work in an apparently normal and healthy condition. His helper testified that the masks furnished by the company to protect employees from the lead fumes were old and were not effective and that at the time the employee became ill the fumes were so bad that he coughed and choked and complained that he could not stand the fumes any longer. The employee became gradually worse and died May 30. The family physician of the employee testified that on several occasions in March 1936 he treated the employee for lead colic and that he treated him again on May 20 for acute lead poisoning and that the cause of the death was acute lead poisoning. This testimony, the court said, showed that at a definite time and place the employee was subjected to an unusual volume of poisonous lead fumes which might have been prevented by furnishing to the employees of the company masks which would have protected them against the fumes. In view of the definition of an occu-

tional disease given to the jury by the trial court, which the appellate court inferentially approved, it was the opinion of the latter court that the employee died from accidental injuries, not from an occupational disease.

The employer contended that the trial court erred in refusing to instruct the jury to find whether or not the employee's death was due to an accident. In the case of *Associated Indemnity Corporation v. Baker*, 76 S. W. (2d) 153, a similar contention was made and the court said:

This was not error. It was shown that the injuries received on that day were the result of inhaling poisonous fumes and gases from the condenser. It was further shown that no other employee in the performance of the same duty had suffered any injury prior to that time. A finding that his injuries were the result of inhaling the fumes is tantamount to a finding that they were the result of an accident.

The judgment of the trial court in the present case, awarding compensation, was affirmed.—*Casualty Underwriters v. Flores (Texas)*, 125 S. W. (2d) 371.

CENTRAL SOCIETY FOR CLINICAL RESEARCH

Twelfth Annual Meeting, Held in Chicago, Nov. 3 and 4, 1939

(Continued from page 440)

Influence of Various Substances (Including Lipocaic and Choline) on Fatty Livers Produced by Scorbuto-genic Diets

DRS. M. A. SPELLBERG and R. W. KEETON, Chicago: Twenty-five of twenty-seven guinea pigs rendered scorbutic by the Sherman-LaMer-Campbell scorbuto-genic diet showed morphologic evidence of moderate to severe fatty degeneration of the liver. Five of these livers, analyzed for total lipids by the Van Slyke monometric method, contained between 11 and 26 per cent of fat. When this diet was enriched by the addition of dextrose and desiccated yeast, the analysis of the livers of six animals showed a fat content of from 4.5 to 12.5 per cent. The normal livers had a fat content of about 2 per cent. That the lack of ascorbic acid is not the sole responsible factor of the pathologic change in the liver was proved by the additional experiment giving adequate amounts of this vitamin to the diets described (ten animals). In the animals on this regimen also fatty livers developed, containing up to 33 per cent of fat. Death was frequently precipitated by a pulmonary infection. Orange juice was no more effective in preventing these fatty livers than pure ascorbic acid, but the animals receiving the fruit juice as a supplement seemed to survive somewhat longer. The only animal that survived more than five months showed cirrhosis of the liver on postmortem examinations.

The lipotropic effect of choline and lipocaic were tested on ten animals. The choline was given as the hydrochloride, 20 mg. daily to each animal. The dose of lipocaic was about 475 mg. daily. Both of these doses are considered adequate for exerting a lipotropic effect. Neither of these substances produced a significant reduction in liver fat. The animals receiving lipocaic showed a liver lipid content of from 9 to 22 per cent, while those on choline showed from 7 to 20 per cent of fat. These values are not significantly below those of the controls.

In addition to adding another approach to the study of liver pathology our experiments suggest that the absence of an unknown or little understood substance in these diets is responsible for these liver changes and that this type of fatty liver is influenced by neither choline nor lipocaic.

DISCUSSION

DR. LESTER R. DRAGSTEDT, Chicago: The gross and microscopic appearance of the liver in the experiments of Drs. Spellberg and Keeton resemble closely the fatty infiltration in the liver which occurs in the depancreatized dog treated with insulin. This latter type of fatty infiltration can be prevented or cured by the oral administration of adequate amounts of fresh pancreas or lipocaic. We have tested the fraction of lipocaic used by Dr. Spellberg and found it to be effective in relieving fatty infiltration of the liver in the depancreatized dog in a dose of from 2 to 2.5 Gm. of dry substance daily. Accordingly it would seem that the smaller amount given by Dr. Spellman should be effective in a guinea pig. We are not sure, however, that the dosage of lipocaic bears a direct relation to the body weight, and for this reason I should like to see the authors repeat the experiment with larger amounts of lipocaic. Whatever may be found with respect to the relation of lipocaic to this type of fatty infiltration in the liver, the observation does not affect the status of lipocaic as an internal secretion of the pancreas. I should like to emphasize this because in the early part of our work some criticism was voiced on the basis of experiments performed on a type of dietary fatty liver produced in normal rats. I will summarize briefly the evidence which makes us believe that lipocaic is a specific internal secretion of the pancreas. 1. The depancreatized dog fed on a mixed diet of protein, carbohydrate and fat is not restored to a normal state by the adequate administration of insulin but exhibits a specific type of disturbance in fat metabolism and commonly dies within three or four months with extensive fatty infiltration of the liver. 2. This disturbance in fat utilization is corrected by the oral administration of pancreas. 3. The beneficial effect of pancreas in this connection is not due to its content of pancreatic enzymes, since fresh active pancreatic juice was found to have no such beneficial effect. 4. The beneficial effect of pancreas cannot be accounted for on the basis of its content of lecithin and choline, since liver and brain, which contain these substances in even greater amounts, exhibit no such beneficial effect. Furthermore, the amount of choline required to produce an equivalent beneficial effect in the depancreatized dog is approximately ten times as great as the amount of choline present in an adequate dose of pancreas. 5. When extracts of pancreas are prepared, the fraction soluble in ether, which contains the fat of the pancreas and practically all of the choline, is found to be inert whereas the fat-free alcohol extract retains the activity of the whole gland. The fat-free alcohol extract has now been sufficiently purified so that a preparation has been secured that is effective on oral and subcutaneous administration in daily doses of from 60 to 100 mg. of dry substance. These extracts contain no lecithin and only insignificant amounts of free choline.

DR. M. HERBERT BARKER, Chicago: Some six years ago I presented slides and work which appeared much like these given today. Those experiments are interesting today because here again another deficiency comes out as marked fatty infiltration. I was interested in seeing the apparent fibrosis of the liver. In our experience there was no fibrotic change that we could see. If the animal was fed nitrogen his liver recovered. Sections of livers of animals before treatment was started revealed high concentrations of fat, and many of them had extensive fibrotic change. I would like to hear comment on the nature and rate of progression of this fibrosis.

DR. PAUL STARR, Chicago: Were there pathologic changes in the pancreas in these animals?

DR. M. A. SPELLBERG, Chicago: This study was not undertaken with the idea of proving or disproving the efficacy of lipocaiic as a lipotropic agent. Our aim was to ascertain whether lipocaiic or choline had any influence on the type of fatty liver produced by us. So far as the dosage is concerned we felt that in view of the opinion expressed in one of Dr. Dragstedt's earlier papers (Dragstedt, L. R.; Prohaska, J. V., and Harms, H. P.: *Am. J. Physiol.* **117**:175 [Sept.] 1936) from 1 to 1.5 Gm. of this extract is sufficient to prevent fatty liver in a dog whose body weight is twenty times or more that of our guinea pigs, approximately 0.5 Gm. used on our animals would seem sufficient. The use of larger amounts would encounter some technical difficulties. We administered the material in aqueous solution with a syringe by mouth. This had to be done forcibly. There was only one guinea pig that had extensive fibrosis, which was true cirrhosis with ascites and edema. This animal survived 154 days. We had only a few others that lived that long, but in the others no fibrosis was detected. It is difficult to keep these animals alive for a long period because they succumbed easily to secondary infection. The rabbit that was permitted to live 142 days did show microscopically increased fibrous tissue in the liver. This animal may prove to be better fitted for the production of fibrosis than the guinea pig. These diets are not deficient in proteins, carbohydrates or fats and are supposed to contain all the accessory food factors except ascorbic acid. The pancreas was normal to gross inspection. The urine was tested a number of times and no glycosuria detected. We have no reason to believe that the pancreas was damaged.

Absence of Toxic Manifestations Following the Parenteral Administration of Promin

DR. RICHARD M. JOHNSON, Eloise, Mich.: The oral administration of promin nearly always results in a moderately severe cyanosis similar to that commonly observed after giving sulfanilamide. Oral ingestion of 25 to 35 mg. of promin (sodium p,p'-diaminodiphenylsulfone-N,N'-di-dextrose sulfonate) per kilogram of body weight each twenty-four hours often resulted in toxic manifestations similar to, but milder than, those reported after large doses of sulfanilamide. The parenteral injection of as much as 300 mg. per kilogram of body weight in twenty-four hours did not lead to the development of cyanosis and did not produce toxic signs or symptoms of any kind in 274 patients given more than 5,000 injections of over 12,000 Gm. The usual parenteral dosage was from 50 to 100 mg. per kilogram of body weight in twenty-four hours.

After oral and parenteral administration, the amount of promin in the blood, spinal fluid, saliva, exudates, transudates and urinary excretion was determined by a modification of Marshall's method for the determination of sulfanilamide. The concentration of promin in these secretions, exudates and transudates closely approximated that present in the blood stream. When promin was administered parenterally, from 95 to 100 per cent was recovered as free promin in the urine from thirty-six to forty-eight hours after administration. A much smaller amount (about 30 per cent) of orally administered promin was recoverable over a more prolonged period (ninety-six hours), and 20 per cent of this recoverable promin was in the conjugated form. This suggests that the substance or substances which produce the cyanosis, toxic manifestations and conjugation may be formed in the gastrointestinal tract.

Dextrose-Citrate Mixture for Preservation of Blood for Transfusion

ELMER L. DEGOWIN, M.D., JOHN E. HARRIS, M.S., and E. D. PLASS, M.D., Iowa City: Rates of hemolysis in samples of human blood preserved in various mixtures at 5 C. for one month were studied. Minimum hemolysis occurred in mixtures containing 10 volumes of blood, 13 volumes of 5.4 per cent anhydrous dextrose in water and 2 volumes of 3.2 per cent dihydric sodium citrate in water. At the end of a month's storage, blood in the dextrose-citrate mixture had hemolyzed only from one twenty-fifth to one fiftieth as much as did blood in citrate solutions alone or in citrate-saline mixtures. During

storage the potassium of the erythrocytes diffused into the plasma, where it attained maximum concentration in about fifteen days. Transfusions into human beings of blood with maximum plasma potassium were accompanied by no clinical, chemical or electrocardiographic evidence of toxicity. The prothrombin disintegrated slowly, remaining above 50 per cent of normal at the end of twenty days' storage when titrated by the method of Smith, Warner and Brinkhous.

DISCUSSION

DR. O. H. ROBERTSON, Chicago: I consider this work timely because of the war in Europe, which may at any moment result in large casualties. In such an event blood transfusions will be employed extensively. During the last war I had the opportunity to try out preserved blood for transfusion using the technic of Rous and Turner, who were the first to devise an effective method for preserving the red blood cells for relatively long periods. Before giving the blood it was necessary to siphon off the supernatant fluid on account of its large bulk and the amount of contained sodium citrate. The sedimented cells were then resuspended in a solution of 2.5 per cent gelatin in physiologic solution of sodium chloride equivalent in volume to the original plasma. This solution has about the osmotic pressure of normal blood plasma. Transfusions with such blood seemed to be just as effective as with fresh citrated blood, and I used blood stored twenty-six days with apparent good results. Requirements for transfusions under war conditions are different from those in times of peace. Wounded men who need transfusion are frequently in a state of shock either with or without hemorrhage, and one must give them solutions that will not escape from the blood vessels since the prime consideration in the treatment of shock is the restoration of the blood volume. The one advantage of simple citration for the preservation of blood lies in the fact that the plasma proteins undergo but little dilution. However, the usefulness of this method is much restricted, since citrated blood begins to hemolyze after ten days. Dr. DeGowin's modification of the Rous-Turner method has removed one of the difficulties in the dextrose-citrate technic, namely that of the bulk and citrate content of the preserving fluid. His data show that the transfusion of the whole mixture of cells and preserving fluid works excellently in conditions of depleted red blood cell volume, but I wish to bring up the question as to how effective this diluted plasma would be in restoring the total blood volume in patients suffering from shock. This point is important in the general applicability of the method. I wonder if the authors have made any observations on the restoration and maintenance of blood volume in conditions of shock after transfusion with this kind of blood.

DR. WARREN B. COOKSEY, Detroit: The considerations that one is primarily interested in are the practical values of this work. I am sure the authors will agree that in the use of preserved blood the usual amount of hemolysis is of no great significance unless very large quantities of blood are given. Because of such studies, I set up our blood bank at Harper Hospital in Detroit on the basis of what I believe are the three major principles to be considered: First, small amounts of blood, frequently repeated if necessary, should give a wider margin of safety; so our blood bank uses only units of 250 cc. of blood and 50 cc. of 2.5 per cent citrate. Second, because of the problems presented by hemolysis, potassium ion diffusion and prothrombin loss, not too old blood should be used; so we convert all blood into useful plasma when it is seven days old. Hence most of our preserved blood is given when only from two to four days old. Third, the mechanical factors, such as an air-tight container and filtration through a fine mesh filter system, can be added safeguards; so such methods were devised. That these considerations seem justified is apparently borne out by the fact that following the administration of the first 700 bottles of blood from the bank only eight reactions occurred, and most of them were extremely mild.

DR. HEINRICH NECHLES, Chicago: Drs. Levinson and Neuwelt and I have studied the possibility of using serum instead of blood transfusions. We have found that in shock

from hemorrhage, even when hemoglobin is low, the most immediate need is not for red cells but for restoration of circulatory volume. Even when blood loss is so great that red cells are needed, immediate transfusion of serum will keep a patient alive until a transfusion with blood has been prepared. Serum is available immediately; it can be put up in sterile containers and may be kept for long periods (eighteen months). It is given without typing, because when pooled serum is injected the agglutinins are neutralized; it need not be kept cold and can be transported easily. In view of the great delay connected with blood transfusions in hospitals without blood banks, as well as at the battle front, we propose the immediate use of serum instead of blood in cases of shock from hemorrhage.

DR. ELIZABETH H. SCHIRMER, Chicago: May I ask whether the authors find that the shape of the flask has any influence on the hemolysis of the red cells?

DR. ELMER L. DEGOWIN, Iowa City: In preserved blood one is always dealing with hemolyzed blood. Hemolysis begins immediately with storage; it does not begin when the blood is shaken, nor is there a hemolysis-free interval of days or weeks. The suitability of this blood for transfusion depends on how much free hemoglobin the recipient will tolerate without danger. The only data available are those of Ottenberg and Fox by which they showed that the human kidney has a threshold for hemoglobin of around 4 or 5 Gm. To answer Dr. Robertson, we have not made any studies on the dilution of serum proteins with reference to shock. We have given the blood-dextrose-citrate mixture to patients in shock and they have recovered satisfactorily. It is assumed that the dextrose disappears from the serum much faster than does the protein, but there is no proof. The question has been brought up about the reaction from blood transfusions. There is a great deal of confusion about this, and the types of reactions must be specified. The causes of none of the types of reaction are known except those due to incompatible blood and those due to the presence of pyrogens. In answer to Dr. Schirmer, we have made no observations on the shape of the flask giving optimal conditions, but we do know that when blood is stored in a flask from which all the air is excluded by displacement with the preservative mixture there will be less hemolysis than when blood is exposed to the air.

Refractory Hemolytic Anemia

DRS. JOHN C. SHARPE and J. P. TOLLMAN, Omaha: From the large, ill defined group of blood dyscrasias termed "splenic" or "hemolytic" anemia, we have separated five cases which are distinctly different from both a clinical and a pathologic point of view. Two men and three women, whose ages varied from 22 to 63 years, had a progressive, subacute course of weakness and jaundice. In each a severe degree of macrocytic anemia, acholuric icterus, reticulocytosis and bone marrow hyperplasia was found. The irrelevant family history, the normal erythrocytic fragility and the absence of spherocytes distinguished this type from familial hemolytic jaundice. Various forms of medical treatment failed. Splenectomy was performed in each instance without improvement. Microscopic studies of the hemopoietic system disclosed a surprising histiocytic reaction within the spleen. The recognition of such a condition as a separate clinical entity is important from the prognostic and the therapeutic point of view.

DISCUSSION

DR. CHARLES A. DOAN, Columbus, Ohio: Analysis of the investigations of the past decade centering about the rationale of splenectomy in a hemolytic type of anemia would seem at present to place such persons in one of four possible etiologic categories: 1. There are patients with a family and personal history and with the physical and laboratory features characteristic of congenital hemolytic jaundice. Splenectomy of these patients, successfully accomplished, always results in a prompt and usually a permanent remission, irrespective of the pre-operative chronicity or acuteness of the clinical manifestations, if all splenic tissue is removed. Such patients, however, have been found to harbor ectopic splenic tissue and to show multiple free accessory spleens more frequently and more exten-

sively than the average normal person. 2. Therefore when recurrences develop in splenectomized patients with hemolytic anemia the tendency is for the physician to transfer his thinking toward other than the splenic mechanisms of hemolysis. A considerable proportion of these patients with recurrences, when subjected to reexploration, show hypertrophied splenic rests with clasmatocytic hyperplasia and excessive erythrocyte phagocytosis comparable to that seen in the original enlarged splenic parenchyma. The first patient successfully splenectomized during an acute hemoclastic crisis in our series of cases of hemolytic jaundice remained entirely well clinically and in normal hemopoietic equilibrium for four years. Then the hemolytic anemia recurred with a gradual but steadily progressive downhill course. When the red count reached 2,000,000, the abdomen was reopened and three small accessory spleens were removed. At the same time a liver biopsy was made and a mesenteric lymph node secured for microscopic study. Only the splenic tissue showed the typical hyperplasia of clasmatocytes with excessive phagocytosis of red cells. The second remission, which followed immediately, has continued until the present time (two years). 3. A third group of patients probably represent either widespread diffuse reticuloendotheliosis involving the Kupffer cells of the liver and macrophages of other organs and the connective tissues generally, or an invisible implantation of ectopic splenic tissue within other organs. These instances occur much less frequently than one might be led to expect, if it is assumed that all the phagocytic mesenchymal elements have a common origin and serve a common function. Elimination by excision, of course, is impossible under these circumstances, and other means and methods of inhibiting or destroying excessive red cell phagocytosis must be conceived and invoked. 4. Anemia due to endogenous or exogenous hemolysin may superficially resemble and occasionally simulate the congenital type of hemolytic jaundice. In one such case in our experience all splenic tissue found at operation was removed, but only an incomplete and transitory remission followed, and at necropsy it was not possible to explain the death on an anatomic basis. The cases reported by Drs. Sharpe and Tollman today would seem to come under the fourth heading. I should like to inquire whether any studies were made on any of the patients cited which would throw light on a possible soluble serum or plasma hemolysin as the basic cause. It is well to have our attention focused on this group of atypical hemolytic anemias which fail to respond to splenectomy and which vary in other essential details from the more classic type of congenital hemolytic icterus. It is quite apparent that they are due to an entirely different mechanism.

DR. S. M. GOLDBAMER, Ann Arbor, Mich.: I cannot understand the reason for calling the anemia macrocytic when I notice that the mean corpuscular volume was normal or below normal. Little is known about the function of the spleen. Its removal may aid the patient but does it alter the disease, as the fragility and the cells remain abnormal? I should like to ask the rationale of removal of the spleen without knowing the etiology of the disease.

DR. MOSES BARRON, Minneapolis: I should like to ask why all these cases were grouped together. The anemias were called macrocytic but it was stated that the cells were small and that definite leukopenia was present. From the description the cases seem to belong to a group which is generally classified as Banti's disease, and I should like to know why they were classified as hemolytic anemias. It was mentioned that they presented acholuric jaundice but it was stated that the patients all had gallstones. Was this true acholuric jaundice or was the jaundice perhaps due to the gallstones? I consider this group as cases of Banti's disease.

DR. M. M. HARGRAVES, Rochester, Minn.: I should like to ask if they had a history suggestive of paroxysmal hemoglobinuria. I have seen three in the past year and have one under my care at present. The histories were suggestive of paroxysmal hemoglobinuria.

DR. FRANK H. BETHELL, Ann Arbor, Mich.: I am interested in the histiocytic reaction observed in the spleens in these cases. Perhaps this reaction was disseminated; I should like to know if an increase in histiocytes was found in the

bone marrow specimens. If so, the hemolysis in these cases might be due to neoplastic proliferation of phagocytic reticulo-endothelial cells.

DR. JOHN C. SHARPE, Omaha: There was no evidence of any accessory spleen or hemolymph nodes present either at operation or at the complete postmortem examinations in the three fatal cases. Dr. Goldhamer asked our rationale for removal of the spleen. Splenectomy was performed only after every other effort had been made to stop the hemolytic process. With regard to the macrocytosis, the average mean corpuscular volume of 110 cubic microns in these cases is definitely above that seen in normal persons in Omaha. Dr. Barron asked whether or not these were cases of Banti's disease. There was certainly no postmortem evidence of this. In answer to Dr. Hargrove's question concerning the presence of paroxysmal hemoglobinuria, we could obtain no history of such a phenomenon nor were there any signs pointing to it at the time of our contacts with the patients. Dr. Bethel asked about the bone marrow studies; we can only say that there is no evidence of a histiocytic reaction within the bone marrow.

Use of Aminophylline (Theophylline Ethylenediamine) to Control Bronchial Spasm Induced by Histamine

RICHARD H. YOUNG, M.D., and ROBERT P. GILBERT, A.B., Chicago: Although the use of aminophylline as an aid to asthma therapy has received considerable attention from clinicians, but little study has been made of the pharmacology of its action on the bronchial musculature. Using the method of Torald Sollmann and A. J. Gilbert, some camera lucida and cinematic studies were made on the reactions of the smaller bronchi and bronchioles in rabbit lung sections. Aminophylline was found to lessen greatly the constricting action of histamine. Further work with guinea pigs showed it to exert a decided protective influence in histamine shock, in which condition it nearly abolishes the severe respiratory symptoms and in many cases seems to prevent the asphyxial death which usually occurs. Experiments are under way to determine its effect, if any, in anaphylactic shock. Other purine derivatives and constricting drugs are also being tried.

Treatment of Chronic Urticaria with Intravenous Injections of Histamine

DRS. H. L. ALEXANDER and ROBERT W. ELLIOTT, St. Louis: During the past few years there have been an increasing number of reports concerning the successful treatment of chronic urticaria with histamine given subcutaneously and by iontophoresis. The rationale of this treatment has never been clearly explained. In the series here reported, histamine has been administered intravenously for the first time to our knowledge as a therapeutic agent. Fourteen patients with chronic intractable urticaria were given this drug by intravenous injection, and eleven secured prompt and complete remission of symptoms. Relapses of three of the eleven occurred but further injections again were successful. Patients in a control series receiving histamine subcutaneously improved, but the results with intravenous injections were by far more prompt and lasting. The technic of intravenous injection was given as well as a discussion of the rationale of this type of therapy.

Physiologic Effects of Histaminase and Histamine

GRACE M. ROTH, Ph.D., and BAYARD T. HORTON, M.D., Rochester, Minn.: We determined the normal response of gastric acidity to subcutaneous injection of histamine. Several days after the response had been accurately established, histaminase was introduced into the duodenum from twenty-five to thirty minutes before subcutaneous injection of histamine. Introduction of the histaminase practically abolished the rise of gastric acidity. Likewise, subjects were immersed in water at 24 C. (75 F.) and the curve of their gastric acidity under such conditions was similar to that caused by histamine. The same procedure was carried out as in the first observations except that the subjects were immersed in water at 24 C. (75 F.) instead of receiving subcutaneous injection of histamine. Introduction of the histaminase abolished the rise in gastric acidity and in some instances definitely caused gastric acidity to decrease. Several days after the normal response

to histamine had been determined, histaminase was injected intramuscularly thirty minutes before the usual subcutaneous injection of histamine. Again the histaminase practically abolished the rise in gastric acidity. In addition, following the administration of histaminase by duodenal tube and by intramuscular injection the other systemic effects from the subcutaneous injection of histamine were practically abolished. We feel that we now have physiologic evidence that histaminase administered to man will inhibit the action of histamine.

DISCUSSION ON HISTAMINE

DR. CARL DRAGSTEDT, Chicago: Experimental analysis of certain hypersensitive reactions such as anaphylactic shock and peptone shock in animals has shown that these reactions are due to an interaction between antigen or allergen and body cells, with a resulting liberation of certain cellular products which in turn produce the characteristic effects of the reaction. Circumstantial evidence indicates that the allergic reactions of man have a similar mechanism. At present, histamine and heparin are the only two cellular products that have been identified in animal experiments. The implication of these observations on the management of allergic reactions is that, in addition to specific desensitization procedures, one can attempt the use of chemical or pharmacologic antidotes to the cellular products apparently most concerned. These papers today indicate three varieties of approach to this end, namely a pharmacologic antagonism to histamine by means of theophylline, a chemical antagonism to histamine by means of histaminase, and the development of what might be called tolerance to the effects of histamine by the repeated administration of histamine itself.

DR. BAYARD T. HORTON, Rochester, Minn.: A man who suffered excruciating headaches for years was relieved by the administration of histaminase. The pain of which the patient complained was limited to one side of the head. It was a constant, excruciating, burning, boring type of pain which involved the right eye, the temple, the neck and the face. It had none of the tic-like qualities of trigeminal neuralgia and there were no trigger zones. The headache occurred with clocklike regularity, particularly at night. Coincident with the onset of pain, the patient invariably described phenomena of vasodilatation which occurred on the same side of the head as the pain. These consisted of engorgement of the soft tissues of the eye as well as injection of the conjunctiva, plugging of the nose, profuse watering of the eye and nose and flushing of the side of the face. The syndrome, which in every respect corresponded to spontaneous attacks, was produced by the subcutaneous administration of 0.5 mg. of histaminase. The patient has remained free from attacks while taking histaminase (T. 360-K).

DR. R. ELLIOTT, St. Louis: Although we began using histamine intravenously on the theory that we could maintain a period of unresponsiveness to the formation of H substance, which in turn is responsible for whealing, we have since been forced to abandon this hypothesis. Since improvement in our cases has persisted for weeks and months, we now suspect that the injection of histamine evokes histaminase and that the latter accounts for the success of this form of treatment.

Changes in Venous Blood Carbon Dioxide Content in Patients Subjected to Rebreathing Experiments

HARRY LANDT, M.D., JULIEN E. BENJAMIN, M.D., and NORMAN JOSEPH, Ph.D., Cincinnati: Rebreathing experiments were made on seven cardiac and seven normal patients at basal conditions. Venous blood samples were collected (stasis free) under oil at minute intervals. Simultaneously gas samples were taken from the rebreathing chamber. The blood and gas samples were analyzed for the oxygen and carbon dioxide content. The gas samples showed almost entire absence of carbon dioxide and of course a progressively diminishing oxygen content. Both cardiac and normal patients failed to show any great difference in the venous blood oxygen content. There was a striking decrease in the venous blood carbon dioxide content in cardiac patients, while the carbon dioxide content in the venous blood in normal patients tended to increase. Explanations are offered for these observed changes.

Current Medical Literature

AMERICAN

The Association library lends periodicals to members of the Association and to individual subscribers in continental United States and Canada for a period of three days. Three journals may be borrowed at a time. Periodicals are available from 1930 to date. Requests for issues of earlier date cannot be filled. Requests should be accompanied by stamps to cover postage (6 cents if one and 18 cents if three periodicals are requested). Periodicals published by the American Medical Association are not available for lending but can be supplied on purchase order. Reprints as a rule are the property of authors and can be obtained for permanent possession only from them.

Titles marked with an asterisk (*) are abstracted below.

Alabama State Medical Assn. Journal, Montgomery

Carcinoma of Esophagus Perforating Aorta. H. J. Schattenberg and J. Ziskind, New Orleans.—p. 615.

Pathologic Anatomy of Human Brucellosis.—Rabson reports a case in which compound fractures of the arm were sustained by a tractor operator aged 28 while working in a farmyard. Soon afterward, and continuing until death eight months later, he had repeated attacks of fever associated with anemia and leukopenia. The macroscopic agglutination test with *Brucella abortus* was positive in dilutions through 1:320. General visceral congestion and evidence of continued breakdown of erythrocytes was observed at necropsy. Granulomas were found in the bone marrow, in the splenic veins and in the enlarged liver and spleen. These consisted of epithelioid cells, lymphocytes and giant cells, many of which were multi-lobated and resembled enlarged megakaryocytes. The granulomas were similar to those described in the literature. The relative rarity of the finding of granulomas is explained by the comparative ease of the body to overcome brucellar infection finally. Only in protracted illness is the characteristic granuloma formed.

Disabling Diseases of Childhood.—Holland says that, in a canvass of eighty-three representative urban communities conducted by the United States Public Health Service in 1935-1936, records of illness and medical and nursing care received in a twelve months period were obtained for 518,767 white children under 15 years of age. Disabling illnesses occurred with greater frequency among children under 10 years of age than among persons in any subsequent period except old age. The duration of the average disabling illness was found to be lowest among children, and except in the period of infancy the rate of recovery from illness was higher among children than among adults. Four in every five disabling illnesses occurring among children under 15 years of age were due to acute communicable diseases or diseases of the respiratory tract. In general, a smaller proportion of the disabling illnesses of children than of adults received care from a physician in the home, clinic or physician's office. In cities with a population of 100,000 and over, one in twenty-four children under 15 years of age had been a hospital patient in the year of survey; in the cities of population under 25,000 the ratio was one to thirty-eight. Over half of the hospital cases among children were surgical; diseases of the tonsils and adenoids alone accounted for about two fifths of the cases. Among children in families on relief and in self-sustaining families with incomes up to the \$2,000 level the proportion of disabling illnesses receiving care from a physician outside the hospital was lower than in families with incomes of \$3,000 and over. This relation was observed consistently in the large, medium-sized and small cities. For all of the diseases of childhood the illnesses of children attended by a physician outside the hospital received more intensive care in families with high than in those with low incomes. The average number of hospital days per child patient, however, was consistently higher among families with low incomes.

Sex Ratios and Hemophilia.—Macklin's curiosity was aroused by the contradictory statements of Eley and of Birch as to alterations in the sex ratio found in families with hemophilia. Eley maintained that transmitters of hemophilia usually have more daughters than sons. Birch stated that the children of transmitters of hemophilia are predominantly male (63 per cent male and 37 per cent female) and that the children of persons with hemophilia are more apt to be female than male. To test the truth of these statements the author analyzed the pedigrees of the transmitters of hemophilia, the pedigree of bleeders and the ratio of unaffected to affected males in families with hemophilia. She found that in families of transmitters collected at random there are more males than females in a ratio of 58.3 to 41.7, owing to the fact that most transmitters are recognized only because they have males in their families in whom the disease develops. When the data are analyzed, computing the number of males one should expect, the excess is found to be apparent, not real. In the families of hemophilic males in which daughters have been said to predominate there was a slight excess of females in a ratio of 54.3 to 45.7. Here again the departure from the expected

value was not outside the limits of what might occur in a sample of this sort. It has been claimed that the ratio of affected to unaffected was much higher than the expected 50:50 ratio. Again, because of the fact that a woman is known for the most part as a transmitter because she has affected sons, the material used to determine the incidence of affected males is weighted in favor of the affected group at the outset. If the incidence is determined only from families of transmitters who are identified by the fact that they had hemophilic fathers, this preponderance of affected males disappears and the ratio of affected to normal is well within the limits of the expected 50:50 ratio. The unaffected actually outnumbered the affected in the series collected, namely 53.2 per cent. Therefore there appears to be no adequate basis for the idea that the sex ratio is disturbed in families bearing the trait of hemophilia, males and females appearing equally in the offspring of transmitters and of affected males, and the defect appearing in about one half of the sons of women who are transmitters.

Value of Bone Marrow Biopsies.—Morrison and Sanwick performed 275 bone marrow studies, obtaining the bone marrow fluid by sternal aspiration. Normal bone marrow was obtained from twenty-eight individuals free of infection, hemorrhage and malignant or other diseases. Bone marrow aspirations were of great diagnostic aid in forty-seven cases in which clinical signs and symptoms and routine blood examinations failed to be of assistance. These were cases of Hodgkin's disease, carcinoma, infections, anemia of pregnancy, pernicious anemia, anerythroplastic anemia, infectious mononucleosis, Gaucher's disease, aplastic anemia, both varieties of leukemia and atrophic cirrhosis of the liver. Observations of leukogenesis in this series confirmed the "shift to the left" theory of Arneith and Schilling as far as the bone marrow was concerned. The most marked left shifts were, in the order named, in acute myeloid leukemias, chronic myeloid leukemias, granulocytopenia, infections and malignant diseases. Slighter degrees of left shift were found in treated pernicious anemia, Niemann-Pick's disease, Cooley's anemia, liver and gallbladder diseases and infectious mononucleosis. Diseases in which left shift was negligible or shifted to the right were polycythemia vera, hemorrhagic purpura, untreated cases of pernicious anemia, pernicious-like anemias and certain cases of arthritis and Hodgkin's disease. A point of marked value in the differentiation of myelosis and granulocytopenia is the unimpaired erythroid activity in granulocytopenia, while in acute myelosis it is definitely depressed. The normoblast-erythroblast ratio is markedly depressed in chronic myeloid leukemias and the granulocyte-normoblast ratio is not as marked as that occasioned by the leukemoid reactions. The most characteristic pathognomonic observation was the unequivocal lymphatic infiltration of the bone marrow seen in lymphatic leukemia. In eighty-five cases in which there was moderate erythropoiesis in the bone marrow there was no evidence in the periphery

of such activity in thirty-six cases. This shows that bone marrow biopsies serve to acquaint one with conditions concerning erythropoietic activity which cannot otherwise be determined in routine peripheral blood examination. Erythropoiesis was most marked in the hemolytic anemias, hemolytic icterus, sickle cell anemia, Cooley's anemia, Niemann-Pick's disease, occasional cases of pernicious anemia and a few cases of Hodgkin's disease. It was slightly increased in malignant conditions, polycythemia vera and infections. Increased erythropoietic activity was absent in leukemias. An increased number of megakaryocytes was found in the cases of hemorrhagic purpura, even exceeding that found in cases of Hodgkin's disease. Certain criteria proving of great diagnostic aid in the study of various conditions was as follows: In carcinoma of the stomach there was always a maturative defect of the erythrocytes. In other malignant conditions the nonsegmented-segmented and granulocyte-erythroblast ratios were frequently increased. In infections there was a constant increase in left shift involving the metamyelocytes and the staff forms. The nonsegmented-segmented and granulocyte-normoblast ratios were also shifted to the left. Since the same is true of malignant diseases, the absence of fever associated with the blood picture would favor a diagnosis of a malignant condition and rule out infection. Certain diagnoses could not have been made accurately except by means of the bone marrow, for example the finding of Gaucher cells, Niemann-Pick cells and plasma cells. The presence of an increase in plasma cells would speak for a multiple myeloma if corroborative clinical evidence is available, since the latter may be present in certain aplastic or myelophthisic anemias.

Testosterone Propionate for Adult Hypogonadism.—Howard and Vest report observations, extending over two years, on the effects of testosterone propionate in sesame oil given by hypodermic injection to twenty-two adult patients suffering from hypogonadism. Development or reestablishment of secondary sex characteristics with induction of normal libido and potentia ensued in all cases. The dosage for adequate maintenance and optimal therapy was 25 mg. twice a week. Smaller doses, if given more frequently, seemed equally effective, but if injections were given only twice a week doses smaller than 25 mg. proved inadequate. Last year following the work of Thorn, the authors began to implant pellets of from 100 to 800 mg. of pure crystalline testosterone in ten hypogonad patients. The patients who had thus been transferred from injection to pellet therapy have reported enthusiastic and gratifying results. No patients have thus far reported overstimulation effects. Since injection treatment leaves much to be desired, because the injections should be given by physicians and two trips a week to a physician's office for life is rather a strenuous program to anticipate, the extraordinary effectiveness of pellets of crystalline hormones implanted beneath the skin is promising.

Thiamin Chloride for Polyneuritis.—Vorhaus cites the results of treating 520 cases of polyneuritis with thiamin chloride. No improvement occurred in fifteen, partial improvement occurred in 189, and freedom from symptoms occurred in 316. The 505 patients who were improved after taking thiamin chloride for an average of nine weeks were kept under observation after discontinuing this treatment. At the present time 315 have had one or more recurrences of their symptoms. Of 170 patients observed up to one year after discontinuing thiamin, 21 per cent showed recurrences. Of the 111 followed for from one to two years after discontinuing thiamin, 71 per cent showed recurrences. Of the ninety-five observed from two to three years 85 per cent and of 123 followed for more than three years 96 per cent showed recurrences. Improvement in symptoms usually begins to be apparent within three weeks and by nine weeks of thiamin therapy improvement reaches its maximum in most cases. Readministration of thiamin in the treatment of recurrences is highly effective. The author believes it possible that some individuals may have a greater normal need for thiamin than can be obtained from a normal diet. For such cases he suggests the term "primary hypothiaminosis."

The Endocrine Mechanism in Abortion.—Browne and his associates determined the excretion of gonadotropic substance, estrogens and sodium pregnandiol glucuronide in twenty-four hour specimens of urine in thirty-five cases of threatened or habitual abortion. In some instances this determination was carried out throughout gestation. They formulate the following theory of the endocrine mechanism in threatened and habitual abortion: The evidence suggests that the ovary and the placenta are two sources of progesterone and estrogens in pregnancy. They interpret the rise in pregnandiol excretion, which occurs from the seventieth to ninetieth days in most normal cases, as being due to the beginning of secretion of progesterone by the placenta. The time at which the transfer of function occurs from ovary to placenta varies in different individuals and in the same individual in different pregnancies. If, however, the corpus luteum ceases to produce progesterone for any length of time before the placenta begins to secrete it, abortion will follow. The time at which a deficiency of corpus luteum hormone is most likely to occur is in the transition period between the ovarian and placental phases (late second and third months). This is the critical period of pregnancy. The cause of many abortions is a faulty gestation from the first; the chorion partakes in this abnormality and produces an amount of gonadotropic substance inadequate to prolong the corpus luteum beyond a certain point. Of other patients whose gestation is less abnormal, the function of the corpus luteum may be prolonged for the usual time and the embryo develop normally, but the placenta may be slow in taking over. Patients in whom either of these conditions occurs repeatedly abort habitually. The use of gonadotropic extracts in early pregnancy when large amounts are present seems likely to have little effect. In patients whose excretion of gonadotropic substance is consistently low, the gestation is already degenerate. In these patients progesterone is obviously useless if given after symptoms of abortion appear. The patients in whom the embryo and placenta develop up to a certain period, but the placenta takes over the function of progesterone formation late or the corpus luteum degenerates early, offer theoretically the most hopeful outlook for progesterone therapy, as in many, if the critical period is successfully passed, the placental function begins and further treatment is unnecessary. The determination of excretion of gonadotropic substance in early pregnancy may enable one to distinguish patients in whom gestation is already degenerate from those for whom treatment might be of benefit. Single determinations are of no value, as some patients having temporary low gonadotropic values in early pregnancy do go to term. Patients who have aborted once or more (without obvious explanation) may yet in a subsequent pregnancy proceed entirely normally. Theoretically, in this group the progesterone should be given before the time of usual onset of symptoms and continued over the critical period. The question of dosage is also difficult to determine, but doses of less than 5 mg. are unlikely to have much effect. This dose should be given daily or every other day and may be increased in the presence of persisting symptoms. Treatment should be concentrated during the period of transfer of the formation of progesterone from the ovary to

the placenta. If pregnandiol assays are available, a definite rise in pregnandiol excretion may be taken as an index that further treatment is probably unnecessary.

Testosterone Propionate for Afterpains and Engorgement of Breasts.—Abarbanel states that 10 mg. of testosterone propionate subcutaneously, given within two hours post partum, prevented afterpains in twenty-two of twenty-five patients. Forty-one of forty-nine patients with severe afterpains experienced adequate relief after 10 mg. of testosterone was divided between the intramuscular and subcutaneous routes. Of fifty patients with severe painful engorgement of the breasts, 10 mg. of testosterone propionate (5 mg. intramuscularly and 5 mg. subcutaneously an hour later) gave practically complete relief to forty-four (92 per cent). No inhibition of lactation was evident in those mothers who continued to nurse their babies.

Surgical Treatment of Hypertension.—Davis and Barker find that the majority of hypertensive patients observed by them respond favorably to the administration of potassium thiocyanate as evidenced by a drop in the systolic and diastolic blood pressures and a fall in the blood cholesterol, total proteins and hematocrit reading. Headache, insomnia, nervousness, fatigue, dyspnea and heart consciousness are relieved, and an actual decrease in the size of the heart occurs. However, there is a small group of patients who are resistant to thiocyanate therapy. The drug must be pushed to the toxic level in treating these individuals before any effect can be obtained, and the lack of a safe margin makes it impossible to control symptoms or blood pressure successfully. In their experience with these patients, bilateral supradiaphragmatic section of the splanchnic nerves alone has failed to decrease their blood pressure or to cause a fall in the chemical constituents of the blood. However, after operation the authors noticed that four patients responded to the administration of thiocyanate. The blood pressure, systolic and diastolic, has shown a definite drop and there has been a decided improvement in the condition of the patients. There has been a parallel decrease in the blood cholesterol, total protein, urea nitrogen and hematocrit readings which compares favorably with the same responses obtained by patients with hypertension who are sensitive to the thiocyanates. The authors believe that section of the splanchnic nerves has in some unknown manner increased the sensitivity of a small number of patients to thiocyanates.

Zinc Peroxide and Sulfanilamide for Burrowing Ulcers.—Meleney and Harvey believe that the ideal treatment for chronic undermining, burrowing ulcers is as follows: When a patient with such a lesion comes to the hospital, after careful anaerobic and aerobic bacteriologic studies, zinc peroxide powder suspended in sterile distilled water in the consistency of a 40 per cent cream should be applied to the wound, care being taken to use effective material, to get contact and to prevent evaporation. This dressing should be removed daily. At the same time, sulfanilamide should be administered by mouth, 1.2 Gm. every four to six hours. If the patient tolerates the medication, and jaundice, destruction of leukocytes and erythrocytes, fever or delirium does not ensue, sulfanilamide should be continued. If toxic symptoms supervene, sulfanilamide should be discontinued. If after one week there are any areas of activity, an operative procedure is required so

results afford conclusive evidence that (1) extreme hypersensitivity to the sting of the bee and other Hymenoptera, with its hazard to human life, can be eliminated, usually for a period of years, by a series of specific inoculations and (2) large, painful and toxic infiltrations from bites of mosquitoes can be similarly prevented.

Blood Preservation and Potassium Diffusion.—Drew and his associates carried out studies to determine whether the previously reported tenfold rise in about thirty days in plasma potassium of preserved blood was a pure diffusion process or whether it was due to actual cell destruction. They state that in heparinized preserved blood there is little or no actual loss in the number of erythrocytes over a period of thirty days. The hemoglobin content remains constant in the total sample, though from 15 to 25 per cent may be found in the plasma. The mean cell diameter of the erythrocytes is reduced about 20 per cent in thirty days. The polymorphonuclear leukocytes are diminished by 50 per cent in forty-eight hours and are amorphous masses in fifteen days. The lymphocytes, monocytes and eosinophils do not disintegrate so rapidly; the latter are particularly well preserved. The thrombocytes rapidly fall to a low level and then remain constant at about 30,000 for some fifteen days.

Germicidal Properties of Oxides of Nitrogen.—From their study of the germicidal action of the nitrogen oxides Williams and Hartgraves find that compressed air passed through an electric arc produces a mixture of gases which is an effective bacteriostatic and bactericidal agent. The bacteriostatic and bactericidal action of this gas is effective in an exposure time of fifteen seconds. The gas is also fungistatic and fungicidal. The vegetative forms of bacteria and fungi are the least resistant to the gas, the spore forms being very resistant. It is believed that the bactericidal power of the gas is due to the formation and deposition of minute amounts of nitric acid and other agents contained in the gas. These as yet have not been analyzed. The gas is easily and economically produced and should find its greatest field of usefulness in the treatment of infected wounds and chronic draining sinuses, particularly osteomyelitis and tuberculous sinuses.

Ultraviolet Irradiation and Vitamin C Metabolism.—Jungeblut and Feiner investigated the relationship that seems to exist between vitamin C metabolism and the effect of ultraviolet rays in the production of disease, when irradiation transcends the threshold of physiologic stimulation. Prolonged ultraviolet irradiation of albino guinea pigs, rabbits and monkeys failed to bring about any change in the tissue levels of vitamin C. When a superficial burn was produced on the skin of guinea pigs by the local application of heat, a more or less marked diminution of the vitamin C stores occurred in the brain, liver, spleen and adrenals. Possibly toxic, histamine-like substances, which have an adverse effect on adrenal function, originate from the burned tissue and require large amounts of vitamin C for their detoxification. This process may be analogous to the well known depletion of vitamin C following the necrotizing action of diphtheria toxin. The intact vitamin C stores after irradiation are of particular interest in view

of Wright's observation that evidence of disturbed vitamin C metabolism occurred only in one individual who showed definite intolerance to ultraviolet irradiation. Evidently a mechanism operates which protects the tissues of some individuals against damage and preserves the vitamin C reserves in the tissues; but the absence of such a mechanism in other individuals, or its breakdown by overdosage of rays, may initiate a derangement of vitamin C metabolism.

Parkinsonian Syndrome from Electrical Injury.—Weinberg reports two cases of parkinsonian syndrome following electrical injury. Both patients have parkinsonian features but differ in certain particulars. One was injured while using the telephone, resulting in deafness on the left side and athetosis. The other was diagnosed as having hemiplegia of the right side with parkinsonism due to a lesion involving the left basal ganglion and internal capsule as a result of electrical injury. The author warns that there is a too ready tendency to diagnose functional disease in such cases. Careful examination should be made for manifestations of organic disease. Because of their great importance and the insufficiency of scientific data on this subject such cases should be reported, so that more may be learned about the neurologic conditions resulting from electrical injuries.

Labyrinthine Fenestration to Improve Hearing.—Kopetzky declares that the problem of surgical relief to the deafened is far from solution. He urges that the surgical work be continued and that physiologists reexamine, in the light of the data obtained by this surgery, the fundamentals of hearing. On the question of what permanent value surgery holds for the deafened, no final conclusion can be made as yet, but there is reason to believe that something is developing which will be of value in the therapy for deafness. Regarding operative therapy (labyrinthine fenestration) for progressive deafness and otosclerosis the author agrees with Campbell and Canfield that the tissue destined to cover the fenestration is less important than the manner of making the fistula. Contrary to what has been said of the heat caused by the polishing burr, he believes that the heat which the burr produces is one of the most important elements in inhibiting bony closure of the fistula. In some of his best results, as far as maintaining a patent fistula is concerned, he so worked the burr that sufficient heat was created to produce a thermal labyrinthine reaction, evidenced by induced nystagmus, long before the telltale dark line had brought the endosteal layer of the canal into view. When, in the earlier cases, he tried not to produce heat, his results he maintains were not as good as when he disregarded this warning and actually strove to produce a degree of local heat with the burr. The size of the fenestration plays a part in the end results. His best

results have been obtained with a fenestration of from 1 to 3 mm. in length. Before operating, it is necessary to know which ear was first involved in the deafness. That probably is the ear at fault, and he thinks that the second ear has lost function largely because there has been a lack of stimulation to the association centers over a long period from the initially involved side.

Bromide Intoxication.—Waggoner and Boyd recognize the beneficial effects of bromides, when correctly used, but they emphasize the equal potentiality for harm when they are given injudiciously. Even in suitable cases, after prolonged administration, the blood concentration may soon exceed the safe level of about 125 mg. per hundred cubic centimeters. The physician must carefully select cases for bromide administration and insist on an adequate fluid intake and sufficient chlorides (at least a daily dose of 15 Gm. of chlorides is necessary when the daily sodium bromide intake is 45 grains [3 Gm.]). As the patient may have already received large quantities of bromide from a previous physician or by self medication, these drugs should never be prescribed without careful inquiry into the history of medication and a chemical examination of the blood or urine. This can easily be done by the method of Belote. Small strips of filter paper are soaked in a saturated solution of fluorescein in 60 per cent acetic acid and allowed to dry. The suspected body fluid is placed in a test tube. To this are added a few crystals of potassium permanganate. After agitation, a few drops of concentrated sulfuric acid are added and the fluorescein paper is held, after moistening with 2 per cent acetic acid, at the mouth of the test tube. The presence of even minute amounts of bromine is at once indicated by a rapid change in color from the original yellow to a bright pink. If bromide is present, the blood concentration should be determined by the Hauptmann modification of Walters' method. If these precautionary measures are carefully observed, bromide therapy is valuable when mild sedation is necessary. Bromides accumulate quickly in the blood whenever the cardiovascular system is disordered and even small doses may cause a bromide intoxication. The increased restlessness and anxiety of these patients, which is due to beginning toxicity, is frequently misinterpreted as a continuation of the original nervous tensional state and the medication is maintained with the ultimate production of severe intoxication. Individuals with mild mental disorders, organic brain syndromes or basically neurotic personalities, that is low psychic reserve, must be considered as already in precarious balance, and potentially intoxicating drugs such as bromides should be used with great caution.

Bile Salt and Biliary Disease.—Ivy and Berman list the activities of bile salts in the economy of the body. They promote the formation of bile, keep fatty acids in solution, aid in the digestion and absorption of fats, facilitate the absorption of iron and calcium, have a laxative action, take an important part in detoxifying bacterial toxins in the intestinal tract, when bile salts are being secreted liver glycogen is diminished and they favorably influence the bile-salt-cholesterol ratio. In the absence of bile salts in the intestine the oral administration of bile salts is indicated to improve digestion and absorption. The role of bile salts in the absorption of vitamins D and K and fats is alone a sufficient indication. The presence of bile pigment in the feces does not necessarily indicate that bile salt is being secreted in the bile. The liver may excrete pigment when it does not form and secrete bile salts. Frequently in biliary tract disease, in the absence of total obstruction, sufficient hepatitis may be present to diminish bile salt synthesis markedly but not to prevent bile pigment excretion. In biliary tract disease without acute hepatitis, bile salts should be administered to flush the biliary passages with a copious flow of low viscosity. Bile salts can be used with the hope of counteracting a tendency toward stasis and its effects and in this way produce and maintain a copious flow of bile through the biliary passages. However, to obtain this effect the patient must have a liver that will secrete bile salts. A brisk flow of fluid through the hepatic ducts tends to prevent ascending infection. Since bile salts are laxative, a lack of bile salts would increase the tendency toward constipation and the increase in constipation would further affect the liver and sphincter, thus possibly setting up a vicious circle that is broken best by the oral administration of bile salts. To what extent the administration of bile salts will change the chemistry of the bile in the gallbladder and will flush out the gallbladder is uncertain. It is possible that "flushing" or a "washing out" of the gallbladder might be obtained by giving bile salts and then fat to empty the gallbladder, repeating the procedure three or four times a day. The authors doubt the wisdom of bile salt therapy in the presence of biliary tract disease and acute hepatitis, except for the purpose of improving intestinal absorption. It is a scientifically directed procedure only when the liver and biliary tract of the patient are proved to be functioning abnormally and bile salt substitution or additive therapy is necessary to aid in correcting the disturbance.

Drug Therapy in Infantile Cerebral Palsy.—In treating patients with infantile cerebral palsy, Nichols and Warson carried out a program of training including hydrotherapy, massage and active and passive exercise. In considering a pharmacologic approach also the hypothesis was advanced that treatment with a drug in the atropine group might reduce the hypertonus, influence the athetosis, speed up the process of training and eliminate the drooling. The drug of choice was scopolamine hydrobromide, which they administered in six cases, with minor interruptions, for two and a half years. The usual maintenance dose was $\frac{1}{100}$ grain (0.0003 Gm.) given twice daily by mouth. There was no change in the treatment program other than the addition of the drug therapy. During the course of this study the scopolamine was discontinued and the effects of three

other drugs, phenobarbital, amphetamine (benzedrine) sulfate and atropine, were tested over two week periods. The authors found that under scopolamine therapy drooling was abolished in all cases, the athetosis was lessened, confidence was increased, relaxation improved and progress in retraining was more rapid. One child learned to walk in three days. No general contraindications to scopolamine were established. In particular there were no increasing tolerance, no annoying side effects and no untoward symptoms even when the drug was suddenly withdrawn after periods as long as nine months. The favorable response to scopolamine came early or not at all. Amphetamine sulfate, phenobarbital and atropine sulfate, which were investigated clinically in the same series, proved disappointing.

Pinworms and Appendicitis.—Botsford and his associates say that seventy-one of 1,343 appendixes removed at the Children's Hospital, Boston, from 1929 to 1939 were infested with pinworms. They resorted to microscopic search as well as to gross inspection. The incidence of appendixes containing pinworms would be higher if such a procedure was followed in a routine manner in other hospitals, as this figure has more than doubled at this hospital since microscopic examination was included. Twenty-six patients had acute appendicitis and pinworm infestation. The cases differed in no way from the usual picture of acute appendicitis in children. Forty-five patients had no inflammatory change in the appendix but had pinworm infestation. All had abdominal pain and all were relieved by appendectomy. Twenty-nine of the thirty patients who had chronic abdominal pain were relieved by appendectomy. Twenty-two patients who had no microscopic evidence of appendicitis but had pinworm infestation of the appendix presented a syndrome exactly like that of acute appendicitis. Pinworm infestation of the appendix cannot be differentiated with certainty from acute appendicitis. It may be suggested by a history of pinworm infestation and recurrent abdominal pain. The mechanism of the mode of action of pinworms in the appendix is unknown. The safest treatment of appendical symptoms due to pinworms is appendectomy.

Treatment of Acne Vulgaris with Estrogen.—Hollander and Schmitt used emmenin (an estrogenic substance of placental origin) in the treatment of forty-one female and nineteen male patients with acne. The patients were from 14 to 25 years of

age and the duration of their acne ranged from two months to twelve years. No patient was under treatment less than three or more than twelve months. As the study was carried on over a period of two years, any improvement due to normal seasonal variation can be disregarded. The diet was not restricted, nor were any local medicaments used. In female patients the estrogenic medication was discontinued during each menstrual period. The forty patients who had no previous treatment and who were not markedly improved after estrogenic therapy received fractional doses of roentgen radiation, the application of a sulfur lotion and a dietary regimen. This was done in an attempt to ascertain if the previously given estrogenic substance might influence the effect of this routine therapy. Fourteen of the sixty patients showed a definitely good response to estrogenic therapy. Ten of these were female and four male. Five patients experienced moderate improvement, twenty-three slight improvement and the remainder were either slightly improved or made worse. Of the forty patients who were given further roentgen therapy, five were markedly improved, twenty-one moderately, eight slightly and six experienced no change. Improvement, if it occurred, always manifested itself by the end of the second month. Seven of the ten improved female patients had a definite association between the acne and the menstrual period. Only one of the fourteen patients who were definitely improved did not have an oily skin. Without exception the oiliness of the skin became much less during the estrogenic treatment. This decreased oiliness was also always observed on the scalp. After the medication was discontinued, eleven of the fourteen improved patients had relapses. The superficial papulocystic acne lesion on an oily skin was the type of lesion most constantly influenced by the estrogenic substance. The duration of the acne in the improved group varied from eighteen months to eleven years. Only one patient showed any untoward reaction: nausea. This patient later tolerated the drug very well. The only positive laboratory observation was a moderate degree of secondary anemia shown by seven of the patients. No patient who previously had normal menses experienced any irregularity, delay or dysmenorrhea of the menses. Two patients who had marked dysmenorrhea found that this symptom was much less severe when they were taking the estrogenic substance. However, a third patient was not helped. Six of the patients who previously had marked irregularity of the menses showed a tendency toward a regular cycle.

Allergic Vertigo.—Crip believes that the incidence of labyrinthine vertigo of allergic origin is greater than suspected. The pathologic physiology is in all likelihood an edema of the various structures of the internal ear. The symptoms depend on which of these structures is edematous. The diagnosis of allergic vertigo is based on the absence of other etiologic factors, the presence of a positive family history of allergy, the presence of associated allergic manifestations (asthma, hay fever, eczema and the like), a history of clinical sensitivity, the diagnosis of blood eosinophilia and positive cutaneous tests and/or the response to epinephrine therapy. Vertigo of allergic origin may occur either as a single isolated symptom or in conjunction with a series of other symptoms such as tinnitus, deafness and gastric manifestations. During the attack the patient may break out in a cold sweat. The attack may be preceded or accompanied by nausea and vomiting. Tinnitus may be unilateral or bilateral and is as a rule high pitched. The impairment in hearing is usually partial and temporary, returning to normal in the interval between attacks. Labyrinthine vertigo may result from causes other than allergy: infections, tumors, toxemia or hemorrhage in the internal ear or cerebral centers. The pathologic physiology of allergic headaches is thought to be that of an edema of the meninges. Many of these patients complain of severe dizziness coincident with the headaches. The vertigo of these patients may likewise be the result of an edematous process of the membranous labyrinth. Adequate treatment is predicated entirely on a correct diagnosis. After all possible causes of vertigo are eliminated, the patient should be subjected to an allergic study. Based on information elicited from such an investigation, suitable changes can be made in the patient's diet and environment. Hyposensitization, whenever indicated, is undertaken.

Serologic Test for Yaws and Syphilis.—The serologic test for yaws and syphilis that Navarro and Gomez discuss was described by Cassili in 1936 and an abstract of his article appeared in *THE JOURNAL*, Oct. 24, 1936, page 1417. The authors present more comparative studies to establish the reliability of the test both as to sensitivity and as to specificity. They used this simple slide test and compared its results with the Kahn and Wassermann tests on 5,390 samples of serum. There was an agreement of 94.8 per cent of all three tests. This test and the Kahn test showed a 1.63 per cent disagreement. With the Wassermann test there was a disagreement of 4.34 per cent. The authors recommend the test as a routine serum diagnostic test for syphilis and yaws, especially in the provincial hospitals and field dispensaries in which well trained technicians and necessary apparatus for other tests are not available. It is further recommended that doubtful or weakly positive results be checked with either the Kahn or the Wassermann test or both whenever possible.

The Healing of Peptic Ulcer.—Cash stresses the fact that, regardless of the method of treatment applied in a given case of peptic ulcer, proof of healing or lack of it is essential. Few ulcers are treated in the early stage and the chronic ulcer with the consequent pathologic changes makes healing more difficult and, even when obtained, permits defects to remain that induce recurrence. That peptic ulcer can be healed is a proved fact. Some ulcers heal without treatment. Many can be cured with diet, rest and medication. The prevalence of ulcers that have undergone repeated courses of treatment without improvement or have reactivated after a period of quiescence is evidence of possible weakness in some phase of treatment. Expectancy in the probable rate of healing of an ulcer with or without slough and exudate has no fixed rule. The majority of active ulcers tend to heal readily, especially gastric; also some duodenal ulcers react to treatment with equal facility. Large active chronic ulcers usually react to direct treatment and heal readily, while the small shallow type often persist, and this type is frequently encountered in the chronic ulcer patient who has suffered varied experiences. Delay occurs more often with the ambulatory patient and is apparently due to excess food with resulting increased gastric secretion and traumatism. Proof for this statement is that, when treatment of similar cases is given in bed, healing occurs in normal time. A braid stain, after disappearance of free blood, exudate and even the crater, indicates that either unhealed scar tissue persists or that a turgescient pylorus with probable hypertrophy is present, or that the gallbladder is

involved or that a severe form of duodenitis may be the source of the persistent braid stain. Location of the stain in relation to pyloric constriction of the braid and the degree of braid constriction will aid in determining where the pylorus is hypertrophied and persistently spastic. When a positive braid stain is obtained before treatment and both tube returns (the procedure of removing slough, exudate and blood from the crater with the use of a tube with fenestrations which are brought in contact with the lesion by measurement taken from the positive test braid) and the x-ray examination are negative, careful study of the case will be required. A positive test braid alone or with tube returns, following surgical closure of a perforated ulcer, indicates an unhealed condition. Proved healing, if followed by recurrence, aids in deciding the need for surgery. In suspected cancer of the stomach or when ulcers have doubtful cancer features, progressive and proved healing exclude such a possibility. After proved healing of a peptic ulcer, digestive symptoms may continue or more likely recur. Hyperacidity, supersecretion, gastritis, duodenitis, pyloric involvement, chronic appendicitis, cholecystitis, gastric hyperesthesia, disease of the colon, adhesions, chronic partial duodenal obstruction, gastroenteroptosis, poor dietetic hygiene, vicious habits, use of alcohol and tobacco are frequently associated with peptic ulcer and may remain and cause symptoms.

Relapses After Sulfonamide Treatment of Gonorrhea.

—Cokkinis and McElligott find that late relapses of gonorrhea after apparent complete cure with sulfonamide derivatives occur frequently. They studied the records of more than 1,200 male and 200 female patients treated with sulfonamide compounds from six months to two years previously. The analysis reveals an incidence of late relapses sufficient to render unreliable any statistics of results based on a relatively short follow-up. The term "late relapse" is used when symptoms return three weeks or more after a successful sulfonamide course and after at least one negative series of tests. Of the total 1,268 male cases of gonorrhea treated, 263 either failed to respond to the treatment or were not seen again before tests of cure were carried out. Of the remaining 1,005 patients who remained well more than three weeks after their last sulfonamide course and who passed one or more series of tests of cure, 118 (12 per cent) have returned with late relapses (112 with one relapse, five with two and one with three relapses). This 12 per cent is not an accurate estimate of the true relapse rate, as a large number of the 1,005 patients defaulted during the follow-up, and some of these must have relapsed subsequently. The 118 relapses are in the authors' opinion all genuine relapses. Another 100 of the 1,005 patients also returned with gonorrhea in the same period: of these, eighty-seven had definite reinfections, while the other thirteen might have had relapses or reinfections. A special analysis of the material shows that: 1. The incidence of late relapses does not vary with the individual sulfonamide derivatives. 2. There is a fall in both early and late relapses when the chemotherapy is delayed until after the first week of symptoms, definitely so in the sulfanilamide treated group. 3. Adjuvant treatment (vaccine) appears to decrease the relapse rate. 4. Apparent rapid cure does not decrease the incidence of relapse. 5. As patients with relapses are more likely to return at a late stage of the follow-up than unrelapsed ones, it is likely that in actual fact there is a gradual fall in the chance of relapse with the passage of time. 6. Gonococci were present in 81 per cent of late relapses treated in the first two weeks of gonorrhea and in 36 per cent of those treated at a more chronic stage. These figures are based mainly on the results of smear examinations. The use of culture studies may have shown gonococci in many more instances of negative urethral or prostatic smears. 7. The many late relapses throw considerable doubt on the reliability of provocative and other tests of cure in cases treated by chemotherapy. The fact that relapse occurred in 118 of their cases after successful passing of at least one series of tests (seventy-one of them passed two or more) indicates that negative tests are not proofs of cure in cases treated by chemotherapy. And yet the fact that 20 per cent of the late relapses were definitely provoked by vaccine, bougie or alcohol from three to six months after apparent complete cure shows that these tests are still of value but that great caution should be exercised in their interpretation. The authors stress the value of repeated examinations (including culture) of the prostatic secretion, as they believe that many postsulfonamide relapses are started by gonococci in the prostate which were rendered only temporarily inactive. A negative gonococcus complement fixation test does not always mean that a patient is cured. Sixteen of the 210 women with gonorrhea had late relapses. On the whole the figures for them are a little more encouraging than those for the men.

Lack of Vitamin K in Infants.—Dam and his associates examined the prothrombin in infants suffering from icterus gravis, hemorrhagic state, and anemia, erythroblastosis and hydrops congenitus. In all a pronounced reduction of prothrombin was found. These cases were compared with a number of normal infants with and without "physiologic" icterus neonatorum. The authors summarize their studies as follows: In normal infants a moderate lack of vitamin K develops during the first few days after birth and disappears within a week. This results in a hypoprothrombinemia, which is the cause of the commonly seen slight hemorrhagic diathesis in the newborn. Its cause must be insufficient supply of vitamin K from the intestine. In diseases belonging to the clinical triad of icterus gravis neonatorum, anemia neonatorum and hydrops congenitus, a considerable hypoprothrombinemia has been demonstrated. Ingestion of vitamin K (together with bile salt) by one of the patients resulted in a rapid increase in prothrombin; one may therefore presume that the hypoprothrombinemia in this case was due to lack of vitamin K. In cases in which a complete lack of prothrombin is seen one day after birth, other causes than insufficient absorption from the intestine must be operating.

Nutritional Deficiency of Vitamin K in Man.—Kark and Lozner report observations on four patients with known deficiency disease of nutritional origin in whom diminished prothrombin levels were incidentally discovered. All four patients had lived alone and had subsisted on diets deficient in fruits and green vegetables. There was no jaundice, but the prothrombin time was found to be prolonged. The patients were each given eight capsules of vitamin K without bile salts by mouth. Each capsule contained 37,500 Dam units. Twenty-four hours after the start of administration of vitamin K the prothrombin time in each case was essentially normal. During the next two days vitamin K was given in the same dosage and after this the prothrombin times were still normal and remained so during the next month, while the patients continued to take the deficient diet without additional vitamin K. Vitamin C therapy was instituted in case 1 after the initial prothrombin observation. Ascorbic acid in a dose of 400 cc. was given daily by mouth, and three days later the vitamin C level of her plasma had risen from 0 to 0.42 mg. per hundred cubic centimeters. At this time a second observation of the prothrombin time was made and this was still greatly prolonged. In cases 2 and 3 treatment with ascorbic acid was not given during the period of observation, and the plasma vitamin C remained at 0. From the foregoing observations it appears that no correlation exists between vitamin C therapy or its level in the plasma and the prothrombin times. The origin of the prothrombin deficiency in these cases cannot be related to biliary obstruction, to biliary fistula or apparently to liver disease. In each case the icteric index, blood fibrinogen and daily urinary urobilinogen were within normal limits. The four cases reported have two noteworthy features: the history of dietary deficiency with the development of scurvy in three and of pellagra and subclinical scurvy in one, and evidence of a prothrombin deficiency which responded to oral vitamin K therapy without bile salts. The evidence seems to point to a

nutritional deficiency of vitamin K as the etiologic basis of the prolonged prothrombin times. None of these patients, however, showed the extreme diminution of prothrombin which has been described in prolonged obstructive jaundice. In view of the fact that the hemorrhagic diathesis associated with prolonged obstructive jaundice develops only when the prothrombin time is considerably longer than in these four cases, it seems doubtful that the prothrombin decrease was the cause of the hemorrhagic manifestations in these cases, for the hemorrhages were classic scurvy and no ascorbic acid was found in the blood plasma. These observations offer further evidence that nutritional deficiency in man is rarely, if ever, confined to a single factor.

Injection of Sodium Salts in Sciatica.—Sutton says that this investigation was instigated by a report which Porter made in 1925. The treatment consists of the administration of both sodium salicylate and sodium iodide in a single solution by intravenous injection. Each injection consisted of 20 cc. of an aqueous solution containing 1 Gm. of sodium salicylate and 1 Gm. of sodium iodide. The solution was prepared as follows: The sodium salts were dissolved in previously sterilized and twice distilled water without warming. The solution was filtered through a Jena glass bowl and put up in 20 cc. sterile ampules, which were quickly sealed, care being taken that the solution did not become too hot. Sterility was further insured by heating to 70 C. for an hour on three consecutive days. The solution is readily decomposed by heat over 80 C. and by light. The ampules were of plain (not colored) glass, so that any subsequent decomposition of the solution would be readily detected. Prepared in this way the solution remains clear for three months or longer. The injections were made slowly with an ordinary 20 cc. record syringe. Any inadvertent injection into the tissues causes great pain, without, however, any subsequent sloughing. The author resorted to this treatment in thirty-two cases of sciatica, of which twenty were primary and twelve secondary. In the twenty cases of primary sciatica, pain ceased usually after about ten minutes. If a second injection was necessary the result was better than that of the first injection. In the twelve cases of secondary sciatica due to some extraneous pathologic condition, pain was diminished but not abolished and a second injection tended to produce less effect than did the first. Any improvement in secondary sciatica is probably due to the analgesic action of the sodium salicylate, but in primary sciatica, in all likelihood "rheumatic," the effect of the sodium salicylate appears to be specific rather than symptomatic. The cases treated this way are too few to justify definite conclusions; nevertheless the intravenous injection of sodium salicylate and sodium iodide does rapidly cure uncomplicated cases of sciatica; on the other hand, its lack of effect on secondary sciatica suggests its value in diagnosis.

*Complications Following Erythema Nodosum in Children. F. Tissot.—p. 627.

Complications Following Erythema Nodosum in Children.—Tissot calls attention to possible complications following erythema nodosum in children. Visceral tuberculous manifestations, such as serofibrinous pleurisy, perihilar and peritoneal irritation, and lobular and perilobular inflammation, occurred in the majority of the twenty cases observed by the author, nine of serious character. Most of these manifestations occurred in the months following the cutaneous incident. For prophylactic measure the author recommends staying home for from six to eight weeks after the cutaneous eruption. If the patient's condition is satisfactory, living in the country or at medium altitude in a mild protected place is advised.

- *1262 F. (Diethyl-Amino-Ethoxy-2-Diphenyl) in Treatment of Anginal Syndromes. A. Clerc and J. Sterne.—p. 1517.
Urinary Infection with Pyocyanic Bacilli. L. Strominger.—p. 1519.
Device for Injection of Conserved Blood. Jame and Grimberg.—p. 1521.

Treatment of Anginal Syndromes.—Clerc and Sterne direct attention to a group of chemical substances capable of influencing certain anginal crises. They cite studies on 1262 F, the diethyl-amino-ethoxy-2-diphenyl, in which remarkable efficacy is combined with relatively low toxicity. It unites the antifibrillatory properties of quinic substances and the beneficial effect of theophylline on the coronaries, but it does not have a depressive action on the heart. The diethyl-amino-ethoxy-2-diphenyl is administered by mouth. The individual dose is 0.05 Gm. and the daily dose amounts to from 0.15 to 0.2 Gm. It is well tolerated, even by subjects with severe cardiac and renal changes. It exerts a remarkable influence on the pains of the anginal type. It proved effective in fourteen of nineteen cases of angina pectoris. Its action was especially favorable in the cases of angina pectoris in which severe electrocardiographic changes existed, which indicated coronary involvement. Doubtless the causal lesion is not removed, but its troublesome effects are attenuated or perhaps forestalled. The medication is purely symptomatic and the duration of the influence may vary. Generally the administration of the diethyl-amino-ethoxy-2-diphenyl must be continued for several months; the doses are gradually reduced until they are stabilized at about 0.1 Gm. a day. Three times it was possible to interrupt the treatment without reappearance of the attacks. Some patients were treated in this manner for from six months to a year. Four times, on the other hand, the efficacy became exhausted, after having been highly satisfactory at first; the attack recurred at the end of several weeks. To avoid this, it has been suggested that the treatment be administered in series of increasing and decreasing doses and if possible with interruptions. Even if the medication is continued for more than a year, harmful effects are absent.

*Experimental Contribution to Epidural and Subdural Hematoma and Therapeutic Value of Dehydration and Repeated Cisternal Puncture. Y. Kabuki.—p. 230.

Epidural and Subdural Hematoma.—Kabuki observed the clinical course and the microscopic appearances of epidural and subdural hematomas which he had produced in dogs for from three to 120 days. The organization of the hematoma of either type takes place from the dural side several days after the operation and is completed in from fourteen to twenty days. Organization of the blood in the case of the subdural hematoma proceeds from the dura alone without the participation of the pia or the arachnoid, whereas in the case of the epidural hematoma in addition to the proliferation from the dura one finds

endothelial cells and various cells proliferating from the bony surface. The author observed the formation of the membrane lined with a thin layer of cells of mesothelial type and considered by many authors to be characteristic for the subdural hematoma, in both the subdural and the epidural variety. Along with the formation of new capillaries, he had observed spaces lined with endothelial cells. These were lined in the early stages with a layer of interlacing fibers but no fibroblasts. The author considered these spaces as blood spaces analogous to formation of new capillaries. Foci of calcification were observed in microscopic preparations from ten to twenty-four days old. Dehydration therapy practiced in one group of these dogs had no effect on the organization of the hematoma. In some of these animals the loss of fluid caused, in addition to shrinking of the brain tissue, alterations suggestive of a beginning degeneration of the ganglionic cells. Organization of the blood began sooner and was completed more promptly in the series in which repeated cisternal punctures were practiced. Among the clinical manifestations the author emphasizes conjunctival hemorrhage, which made its appearance on the first postoperative day, as a rule, and which disappeared by the seventh to tenth day. This symptom had not been previously mentioned. The cerebrospinal fluid showed distinct differences in the two types of hematoma. There was only a mild increase in the cell count, and this soon returned to normal, and no other pathologic observations in the epidural type, while in the subdural the cerebrospinal fluid was distinctly hemorrhagic. Xanthochromia and a positive Nonne-Appelt reaction were present and the increased cell count persisted for as long as two weeks. The animals exhibited clonic spasms, convulsions and pareses of the lower extremity of the corresponding side, as a rule. Secondary bleeding was not unusual and took place, as a rule, between the dura and the hematoma, in one case thirty days after the operation. The organization process of both types of hematoma is typical. It consists of proliferation of spindle-shaped reticulum cells which form interlacing connective tissue fibers.

Phosphorus Content of Raw and Heated Milk.—Weingärtner points out that Catel had demonstrated in experiments on goats that feeding with heated homogeneous milk results in disturbances in the mineral metabolism. The question arose as to what factors are involved in this metabolic alteration that is produced by heating the milk. Since according to some investigators it is the ultrafiltrable portion of phosphorus and calcium that is absorbed and thus becomes important for the organism, the author decided to investigate whether this portion is reduced by the process of heating. The phosphorus and calcium content were determined in raw and in heated (three minutes at 100 C.) breast and cow's milk. Although it was realized that defatting of the milk involves a slight loss of phosphorus and calcium, the determinations were made on defatted milk in order to prevent a possible undesirable lipolysis and a stopping up of the filters with fat. The author found that the phosphorus content of the raw and heated cow's milk is approximately the same but that in heated breast milk it is 28 per cent lower than in raw breast milk. The decrease of phosphorus in the ultrafiltrate of heated breast milk in comparison with the phosphorus content of the ultrafiltrate of raw breast milk was 40.5 per cent. The decrease of phosphorus in the corresponding ultrafiltrate of cow's milk amounts to only 1.4 per cent. It is probable that the considerable decrease in the phosphorus content of the ultrafiltrate of heated breast milk is due to the fact that by the sterilization (heating) acid-soluble organic phosphorus is transformed into complex compounds and that a portion of the acid-soluble anorganic, ultrafiltrable phosphorus is transformed into colloidal compounds which do not pass the filter. The calcium content of

heated breast milk is reduced 19.3 per cent in comparison to that of raw breast milk. The decrease of calcium in the ultrafiltrate of heated in comparison to the calcium content of the ultrafiltrate of raw breast milk is only 0.84 per cent. The corresponding decreases in cow's milk amount to 0.5 and 0.4, respectively. The author concludes that the results of these investigations make understandable the disturbances in the mineral metabolism of prematurely born infants who are fed with sterilized breast milk.

Anthropologic Value of Fingerprints. J. Dankmeijer and R. C. Renes.—p. 2873.

Acute Appendicitis in Netherland East Indies.—Fossen and Boeke state that, from the first of March 1934 to the first of March 1939, 175 patients were treated for acute appendicitis in the Central Civil Hospital in Batavia. These 175 patients with appendicitis were observed among 13,000 patients; that is, the appendicitis cases amounted to 1.3 per cent of the total number. Among the 13,000 patients there were about 1,600 Europeans, 2,400 Chinese and 9,000 natives. The number of cases of appendicitis for these three racial groups were seventy-two, fifty and fifty-three, respectively. Thus the incidence of appendicitis among the Europeans was 4.5 per cent, among Chinese 2 per cent and among the natives only 0.6 per cent. However, the authors point out that anatomic pathologic studies on appendixes of the different racial stocks have revealed that signs of inflammation occur in a large percentage of the appendixes of natives as well as of Chinese; in fact, their morbidity is even higher than that of Europeans. Thus it seems that appendicitis is as frequent in the East Indies as in Europe, but it causes clinical manifestation much less frequently there than in Europe. Of the seventy-two Europeans who had appendicitis, forty-two were men and thirty were women; among the fifty Chinese, forty-five were men and five were women, and of the fifty-three natives, forty-eight were men and five were women. Thus among the natives and Chinese appendicitis is much less frequent in women than in men. Analyzing their cases according to age groups, the authors found that the incidence of appendicitis is highest in the age group between 20 and 30.

Influence of Salyrgan on Volume of Blood.—Lopes Cardozo made studies on patients with heart disease who, in spite of optimal treatment with digitalis, still had severe edema. He determined the volume of plasma by means of the blue dye-stuff T 1824 before the onset of the salyrgan treatment and after the edemas had disappeared, which required as a rule from seven to ten days, during which time the weight decreased by from 10 to 20 Kg. The author records observations on eight patients. 111:

He found that salyrgan treatment causes a reduction in the volume of blood. The diminution in the volume of plasma is accompanied by an almost parallel reduction in erythrocytes, so that the relative cell volume shows a tendency to remain normal. Even during salyrgan diuresis a gradually progressive reduction of the plasma volume has been observed. Probably this is in part responsible for the drop of the urea clearance that has been found during and shortly after salyrgan diuresis.

Acute Polyarthritits as Symptom of Tuberculosis.—Heimbeck reports the case of a woman aged 21 with tuberculous anamnesis in the father's family. The patient had been in good health until the sudden development of pain in the knees, left elbow, right hip and finger joints. The ankles, like the fingers, were swollen but not painful. Examination disclosed no abnormalities in the body, urine or temperature. Pirquet's test was tuberculin negative after forty-eight hours. Initial therapy before hospitalization consisted of rest and doses of acetylsalicylic acid. The pathologic condition evolved through an alternation of varying articular pains and their subsidence, in weekly intervals, with the sedimentation rate fluctuating accordingly. Another tuberculin test made six weeks after the initial appearance of the symptoms resulted in a maximal tuberculin positive reaction with vesicles. A roentgenogram taken on the same day failed to disclose the existence of a tuberculous lesion. The patient was kept in bed and managed with a combined arsenic and acetylsalicylic acid therapy. After a month (ten weeks after the appearance of the initial symptoms) a roentgenogram disclosed a clearly delimited compact infiltration the size of a small pea in the second intercostal space. A roentgenogram repeated two weeks later disclosed a right pleural effusion with no change in the infiltration. A further examination two months subsequently disclosed a diminution of the pleural effusion and incipient cicatrization of the pulmonary lesion. Control observations made about three and one-half months after this showed a physically normal condition and a pulmonary abnormality scarcely traceable in the roentgenogram. At no time were coughing and expectoration noted. The author regards the case as one of primary tuberculosis so recent in origin that neither the tuberculin test nor the roentgenogram indicated any abnormality until the infection had developed sufficiently. The diagnostic picture proceeded from a complete tuberculin anergy and negative x-ray evidence to a condition of maximal allergy within six weeks, with x-ray determination of the tuberculous focus as late as four weeks after this. Nonspecific articular abnormalities are not rare phenomena of tuberculous toxicity and have been variously interpreted in the literature. The new feature, according to the author, in this case is the appearance of initial articular symptoms in tuberculosis of a primary character. He thinks that specific primary toxins of tubercle bacilli may well exist in the absence of a tuberculin positive reaction. Experience with BCG vaccine therapy indicated to him that gross abscesses can exist months before cutaneous allergy can be demonstrated.

Roentgen Therapy in Insertion Pains.—Mustakallio and Laitinen report excellent results obtained by roentgen treatments in forty-seven cases of rheumatic disorders at the insertion site, chiefly epicondylitis (twenty-one cases) and calcaneitis (twenty-one cases). The average age levels for both men and women

in epicondylitis were 44.8 and for calcaneitis 32.4. The average duration of illness before treatment was respectively six and seven months. All the cases of epicondylitis, with the exception of two, were lateral. Calcaneitis affected chiefly persons with flatfoot abnormality. Symptoms of epicondylitis consisted of actual pains, sensitivity to pressure, local swelling and pain on exertion, while patients with calcaneitis suffered pain in the standing or walking position. Both conditions caused partial incapacity for work. X-ray examination disclosed modifications consisting of small atrophic spots on the surface of the bone at the insertion site which gradually acquired uneven contours and showed small osseous spurs projecting in the direction of the tendon. Calcification in the vicinity of the insertion site was less frequent and apparently when it did occur was found in the tendon. In several cases x-ray examination showed that not only the bone at the insertion site but also the tendon terminating at the insertion site was affected, clear evidence of periosteotendinitis. X-ray examination of the heel bone disclosed periosteal changes consisting of spur formations at the tuber calcanei, which were manifestly of earlier origin, and of small atrophic spots such as rarely appear in normal conditions. Treatment consisted of single skin doses of from 100 to 150 roentgens applied twice at intervals of one or several days and was repeated, if necessary, every two weeks. Most cases promptly yielded to the first series of treatments and did not require further application. The patients were able to resume work after a few days. Subsequent inquiries extending over six months to six years, to which thirty persons responded, disclosed twenty-three cures (ten of the patients having been ill six months or longer before treatment), four improvements enabling work resumption, two relapses and one failure. According to the authors, insertion diseases merit greater attention because of the economic loss involved in inability to work. They stress the advantage of roentgen therapy over surgical intervention in painlessness, gain of time and economic saving. Operation consists of making a small incision in the insertion tendon of the lateral epicondyle and through immobilization effecting a cure, the procedure requiring about ten days.

Spondylarthritits Ankylopoietica.—Lassen says that this disorder, which occurs chiefly in men, is now considered rheumatic. In spite of definite symptoms it is often not recognized until fairly late. There are inflammatory changes in the peri-articular connective tissue with growth of connective tissue into the small joints of the spinal column, with secondary calcifications after connective tissue ankylosis for a longer time. Corresponding changes take place in the sacro-iliac articulation. X-ray changes in the spinal column cannot be established until after three to five years, but changes in the sacro-iliac articulation are demonstrable in about a year. By x-ray examination of this articulation diagnosis can be made so early that an effective therapy can be introduced. Treatment consists of long continued physical therapy, warm baths of different kinds with light treatment and other strengthening and stimulating treatment, together with rest and massage. Under proper treatment the patient is able to work in spite of considerable ankylosis of the back, if greater deformities under development of the ankylosis can be prevented. The author reports that of seventeen patients (sixteen men, one woman) with spondylarthritits ankylopoietica treated in the last four years all but one admitted under various other diagnosis, physical therapy as indicated resulted in improvement in the ten. In six the symptoms had set in before the age of 20, in only one as late as at about 40. The average duration before diagnosis was about six years. In all cases there was pain in the legs, hips, loins and back and stiffness of the back; in six there was considerable anemia. The sedimentation reaction was pathologically increased in all cases. The general condition was affected in eleven.

THE PATHOLOGY AND ROENTGENO- GRAPHIC MANIFESTATIONS OF PNEUMOCONIOSIS

LEROY U. GARDNER, M.D.

SARANAC, N. Y.

To the pathologists who coined it, the term pneumoconiosis was useful to describe all pulmonary reactions due to the inhalation of dust. Under the impetus of compensation laws this group of conditions has received so much attention that today pneumoconiosis is almost a household word. But too few are aware of its original significance and even some medical writers use it interchangeably with the specific term silicosis. As a pathologist I prefer to retain the original meaning and use pneumoconiosis as a generic term to describe all forms of pulmonary reactions to inhaled dust, with no implication as to character, severity or effect on function. The two clinically important forms of pneumoconiosis that are known as silicosis and asbestosis are respectively due to inhaled free silica and asbestos dusts. Other forms have been given special names to indicate the kind of mineral that produces them, but such terms have little practical significance because most pure substances other than free silica and asbestos cause little irritation and provoke essentially the same kind of tissue changes. Available information would make it more logical to classify most of the other known pneumoconioses in two general categories. Those which are characterized by appreciable degrees of fibrosis will yield free silica on analysis and hence should be designated as "modified silicosis." For the remainder I would suggest the name "benign nonspecific pneumoconiosis."

Illustrative of the latter are simple anthracosis and siderosis produced by inhaling relatively pure coal or iron dusts. By themselves these minerals provoke no significant fibrosis but merely pigmentation, which has no influence on pulmonary function. When they are mixed with free silica there is a fibrous reaction, but it is due to the contaminating silica. The resultant diseases are then more properly designated as anthracosilicosis and siderosilicosis.

Badham¹ suggested the term "silicatosis" to designate reaction to any silicate dust, but as there are hundreds of different silicates and only the fibrous varieties, collectively called asbestos, are known to provoke serious reaction his suggestion has not been generally adopted. In nature some silicates are commonly mixed

with quartz, but it is probably the latter which is responsible for pulmonary damage. Hence reactions to such dusts are properly designated as modified silicosis. Possibly other silicates whose effects have not yet been evaluated may subsequently prove to be dangerous in their own rights, but if they are it will not be because they are compounds of silicon but because of some special peculiarity of structure or composition.

In the temporary category are the pneumoconioses that are known chiefly from shadows cast on a roentgenogram. They may have a foundation of pathologic reaction, but it has not yet been adequately defined. However, the changes in the film are associated with so few authentic symptoms that their influence is viewed with skepticism. Here belong the so-called baritosis seen in men who are exposed to dust of barium sulfate and the false nodulation of arc welders. The former, described by Arrigoni,² may be nothing but the shadows of compact collections of radiopaque barium particles in the lungs. Likewise, Enzer's³ report of a single autopsy on an arc welder makes it seem probable that similar collections of iron particles rather than foci of fibrous reaction are responsible for the "nodular" shadows seen in occasional roentgenograms.

Finally there is the whole group of reactions to organic dusts that are properly included under the term pneumoconiosis. One form said to be due to cotton fiber has been named byssinosis but no good description of its pathologic manifestations can be found in the literature. In general it is assumed that most of the organic dusts may cause bronchitis with or without sensitization phenomena resulting in a variety of allergic symptoms. Moreover the reaction to dust composed of living organisms is in one sense a pneumoconiosis, but such conditions are generally classified as infections. They are beyond the scope of this paper. Likewise, definitely toxic dusts such as lead are excluded. Even without this group it will be appreciated that the term pneumoconiosis includes many different conditions and does not necessarily imply disabling disease of the lungs.

The first paper of the series¹ dealt with specific causes. It reviewed some of the complex factors which govern the behavior of fine mineral particles suspended in air and attempted to point out how they influenced the inhalation of dust. It discussed the varying capacities of different kinds of minerals to provoke reaction once they had accumulated in sufficient quantities within the lungs and indicated that some might inhibit the dangerous effects of free silica. It considered the influence of coexistent infection and the

subject of individual susceptibility with a review of the factors proposed to explain this phenomenon.

The present paper will be concerned with the pathologic reactions to different minerals in normal and in infected human lungs. It will take up the evolution of the various disease processes and, when possible, describe the shadow pattern cast on roentgenograms of the lungs.

PROTECTIVE MECHANISMS

When one considers that in quiet respiration the average human being inhales some 12,000 liters of air every twenty-four hours and then recalls the varying degrees of atmospheric pollution created in our industrial civilization, it is apparent that the lungs must be protected against dust or they could not escape becoming clogged with foreign material. In all the higher animals, at least, two sets of mechanisms have developed designed to keep their lungs clean: one prevents dust particles from entering the lungs; the other removes the particles that elude the first barriers.

Dust particles are caught in the mucus secreted by the membrane lining all parts of the tract. Ciliary action then transports them to the nasopharynx, from which they are excreted.

Lehmann⁵ has suggested that such activities play only a minor role in the removal of dust in the nose and thinks that the shape of its cavities has much more effect. He has pointed out that the nasal passage consists of dilated anterior and posterior portions separated by a narrow constriction in the vicinity of the turbinates. He recalls that when dust-laden air is blown through a glass tube with a central constriction the particles all come to rest in the distal, dilated portion owing to the sudden cooling and expansion of the air. He believes that deformities due to faulty development, disease or injury change the shape of the nasal cavities and lower their efficiency for the removal of foreign particles. The technical difficulties encountered in measuring the quantities of dust retained in the nose have prevented confirmation of his observations.

It is generally assumed that at least half of the foreign matter in inspired air will be removed by these mechanisms in the normal nose, trachea and bronchi. There has been considerable speculation but little proof of the influence of disease in these organs. It is argued that the chronic bronchitis often associated with silicosis probably permits unusual quantities of dust to enter the lungs. As a matter of observation, the lungs of animals with purulent bronchitis actually contain much less dust than those of normal ones exposed to the same concentration. The heavy plugs of secretion in the larger air passages mechanically prevent the ingress of foreign particles. It has also been pointed out that one of the manifestations of chronic bronchitis is epithelial metaplasia with the formation of a smooth lining membrane that should permit freer passage of dust particles into the lungs. One should remember, however, that such metaplasia is practically never generalized and that it almost always involves one or two bronchi immediately adjacent to a focus of chronic disease inside the lung. Such a condition might account in part for the unusually heavy deposits of dust in the localized pulmonary focus of infection, but it would have little influence on the rest of the lungs. Thus some phases of tracheitis and bronchitis may be protective mechanisms, and until their influence has been evaluated it is best to refrain from inference.

The discussion thus far has dealt only with particulate foreign bodies, but where fibrous materials are concerned the upper respiratory protection would seem to be less adequate. Since asbestosis constitutes one of the dangerous forms of pneumoconiosis to be discussed, certain exceptions to what has been said must be noted at this point. Apparently many of the long asbestos fibers succeed in sliding over the surface of ciliated epithelium, for the lungs contain plenty in excess of from 10 to 20 microns in length, and occasional ones as long as 200 microns have been discovered. These fibers seem to pass through the smooth walled bronchi quite readily, but when they reach the respiratory bronchioles the alveolar pouches given off from the sides of these tubes entrap and retain them. Whether the same is true of all fibrous foreign bodies has not been established.

Little is known about the primary distribution of inhaled foreign particles within the lungs or the factors which govern it. It has been observed that carmine particles reach the subpleural alveoli within half an hour after animals have been exposed to heavy atmospheric suspensions of such material. The path of these particles, the influence of tidal and residual air, the effect of deep or shallow breathing all remain to be investigated. Posture and specific gravity probably have little influence on particles as small as 3 microns or less in diameter.

Secondary deposition of inhaled inert particles, on the other hand, has been investigated more extensively. Gross inspection of the lungs often shows streaks of pigmentation in the pleural surface, arranged in bands that are opposed to the intercostal surfaces, with little or no deposit in the intervening grooves formed by the ribs. Likewise the diaphragmatic surfaces are practically free of dust. Such distribution implies that pressure of overlying parts has prevented local deposition. Furthermore the heaviest deposits tend to occur in the upper two thirds of the pleura, suggesting that the greater excursion of the lower portion of the lung may have limited retention. Examination of a section of the lung is not so informative because the various structures are cut in so many planes. However, inspection with a lens will usually demonstrate fine linear deposits along the connective tissue septums, between lobules and around the medium sized blood vessels. The walls of the bronchi always show much less pigmentation. In very severe cases of pure anthracosis the entire lung may be uniformly black. Almost always the lymphoid tissues within the lungs and those of the nodes at their root are more or less heavily pigmented.

To understand this distribution of inhaled pigment one must appreciate the mechanisms provided for its elimination from the air spaces. These mechanisms include the mobile alveolar phagocytes and the pulmonary lymphatic system.

Alveolar Phagocytes.—These originate in the walls of the air spaces, become detached and are capable of independent amoeboid activity. Their origin is still debated, but it is my own belief "that they belong to the general group of wandering cells of connective tissue, variously known as histiocytes, clasmatoocytes and the like. Others think that they may be modified epithelial cells from the alveolar lining and some observers consider them monocytes that have wandered out of the blood vessels. This is not the place to discuss the evidence for these views. Whatever their origin, these

6. Gardner, L. U., and Smith, D. T.: *The Origin of the Alveolar Phagocyte*, *Am. J. Path.* 2: 445-460 (Sept.) 1927.

cells appear in the alveoli in numbers corresponding to the quantities of inhaled foreign bodies. As chance contacts are established, the particles of dust are ingested by the cells.⁷ The process may be repeated so often that many phagocytes contain enough foreign material to obscure their internal structure. Often the cell enlarges as it engulfs more particles. The phagocyte moves slowly over the inner surface of the air space until it finally comes to rest in the vicinity of a lymph vessel. Whether there is any force which guides its course has never been established.

Lymphatic System.—The final stage in the process of freeing the air spaces of accumulated foreign particles is a function of the lymphatic system. Space forbids a complete description of the pulmonary lymphatics but it should be recalled that the lungs are provided with two sets of lymph vessels, one coursing through the pleura and another located in the connective tissue sheaths of blood vessels and bronchi. The superficial and deep sets communicate with one another by means of short thick vessels situated in the septums between subpleural lobules; these permit lymph to flow from the interior of the lung to the pleura in case of obstruction in the deep system. Wherever lymphatic trunks communicate with one another inside the lung there are masses of lymphoid tissue. These points are located in the pleura, at the distal ends of the alveolar ducts and where blood vessels or bronchi bifurcate. The lymphoid nodules increase in size as the hilus is approached. Both superficial and deep lymphatics discharge most of their lymph into large nodes located about the bifurcation of the trachea, referred to in this communication as the tracheobronchial nodes. Efferents from the lower portion of both lungs pass through the crura of the diaphragm to nodes situated along the esophagus and cardiac end of the stomach.

Dust particles are carried into the lymphatic vessels either by mobile phagocytes or in the free state. The mechanism in the latter case is not understood.⁸ Many come to rest in and about intrapulmonary lymphoid deposits; more are borne along and deposited in the tracheobronchial nodes. In experimental animals the first deposition is in the nodes, and as these structures become filled increasing quantities are found in the successively peripheral nodules of pulmonary lymphoid tissue. Strachan and Simson⁹ described similar deposition in human lungs.

Not all the inhaled material is removed to the lymphoid tissues; in most lungs considerable pigment is also found in the areolar tissue surrounding the lymph vessels. These deposits often seem to be made up of elongated collections of free particles packed between the fibers of connective tissue. Haythorn,¹⁰ however, has demonstrated that many of these particles are actually contained within the bodies of compressed phagocytes. On production of an edema that separates the fibers and allows the "dust cells" to assume their more familiar spherical form, the intracellular distribution of the particles again becomes recognizable.

It is not known whether such perilymphatic deposits are composed of material that is temporarily stored in

the areolar tissue until it can be carried off through the lymphatic vessels or whether, having entered a vessel at some peripheral point, it has subsequently escaped into the surrounding tissue. In any event such deposition occurs in the pulmonary framework, a location where the foreign body can exert no influence on respiratory function.

These perilymphatic and lymphoid tissue accumulations of particles are responsible for the pigmentation seen on gross inspection of the lungs. On the pleural surface the delicate tracery of lines is made up of accumulations in the areolar tissues about the superficial lymph vessels; the focal collections occur in lymphoid tissues at the junction of communicating and superficial lymph vessels. Similar relationships exist in the depths of the lungs. The generalized diffuse pigmentation often seen in the lungs of persons dying during exposure to dust is due to free and phagocytosed particles still within the air spaces. In cases in which diffuse pigmentation is still present years after exposure has ceased, the "drainage" mechanisms have been inadequate to remove the excess of inhaled particles. However, the next section will indicate that even within the air spaces most kinds of particles produce no apparent changes that could interfere with respiratory function.

THE HISTOGENESIS OF PNEUMOCONIOSIS

Phagocytosis and Concentration of Dust.—It is in the phagocytes that foreign bodies first exert their specific influences on living cells and that differences due to physicochemical composition of the irritant become manifest. Inert substances like garnet, silicon carbide and aluminum oxide have no effect on the structure of the cell, although they may retard or stop its locomotion by their mass within its cytoplasm. Frequently such overloaded phagocytes are found within the alveoli years after exposure to dust has ceased.¹¹

Toxic free silica, on the other hand, quickly injures the phagocytes, and its effect is directly proportional to the number and size of the ingested particles. Such effects are most readily observed in experimental animals killed at intervals during exposure to high concentrations of siliceous dust, but they can also be seen in human cases of rapidly developing silicosis. No changes are visible in the cell that has taken up a few large fragments 4 or more microns in diameter, but when the particle size is under 3 microns the number ingested by each cell is much greater and, as a consequence, the amount of surface in contact with cytoplasm is greatly increased. Degenerative changes closely simulating those in the "epithelioid" cells of tuberculosis then become manifest. The cell enlarges, droplets of visible lipoid appear in the cytoplasm and the elements stained supravitaly with neutral red are rearranged to form patterns indistinguishable from those in tuberculous epithelioid cells.¹² With the proper concentration of the irritant, the nucleus divides repeatedly as the cytoplasm increases in extent; the result is a giant cell in every way comparable to the Langhans giant cell of tuberculosis. In animals injected with extremely fine silica, such giant cells may attain astounding size with several hundred nuclei. Under very potent stimulation the cell is killed and undergoes

a process that Mavrogordato¹³ described as "mummification." It retains its normal size and the limiting membrane is intact, but all internal structures fail to stain with histologic dyes. Some of these "ghost cells" preserve their identity, but others probably break up and liberate their contents, which are then taken up by new phagocytes.

The great similarity between the effects produced by crystalline silica and tubercle bacilli¹² has puzzled many observers, but Fallon¹⁴ has proposed a hypothesis and already published preliminary experiments which may contain the explanation. He conceived the idea that the action of both these primary irritants on the phagocytes liberates toxic phospholipids and that these substances are responsible for the further proliferation that results in the formation of the granulomatous nodule. He demonstrated that such lipids, at least partially freed of silica, were actually capable of producing tubercles.

Finally there is a suggestion that small quantities of silica taken up by phagocytes tend to stimulate ameboid activity,¹⁵ for in early silicosis the cells seem to migrate to lymphoid tissue more rapidly than in any other form of pneumoconiosis. However, it is difficult to be certain whether the clusters of cells observed in and about the nodes have actually migrated there or whether new ones may have proliferated under the stimulation of the toxic material.

The response of the phagocytes to fibrous asbestos requires special comment, as it is treated in a different manner from particulate material. The fibers are often too long to be completely ingested by a mononuclear or giant phagocyte. Frequently one end will project beyond the border of the cell, or sometimes several phagocytes will attach themselves to a single fiber. Giant cells do not migrate far and most of them are either applied to the walls of the bronchiole or at most have penetrated its substance. It is practically impossible to discover fibers or asbestosis bodies in the more remote intrapulmonary or mediastinal lymphoid tissues.

For all dusts the mechanisms of phagocytosis and concentration have many common features but, as indicated, even the initial cellular responses are modified by the properties peculiar to the three classes of minerals under consideration. Because these changes are microscopic, it has been convenient to consider them together. We are now in a position to consider the three generally recognized anatomic forms of reaction to mineral dusts under the headings benign nonspecific pneumoconioses, silicosis and asbestosis.

THE BENIGN NONSPECIFIC PNEUMOCONIOSES

In the category of benign nonspecific pneumoconiosis is included every known reaction to mineral dust except that to the soluble poisons such as lead, the specific diseases, silicosis and asbestosis, and "roentgenologic conditions" such as baritosis and the pseudonodulation of arc welders, previously mentioned.

We have seen that the action of the alveolar phagocytes and the lymphatic system tends to concentrate particulate mineral matter, regardless of its chemical composition, in the lymphoid tissues of the lungs and mediastinum and that there are also appreciable accumulations in the areolar tissues about lymphatic trunks.

The reaction that will be produced in these locations is determined by the physicochemical properties of the minerals concerned. As shown in the first paper, on etiology,⁴ most of them exert no appreciable effects on connective tissues; a few can produce low grade chronic inflammation which is not progressive and does not terminate in fibrosis appreciable on gross examination. All these reactions occur in the framework of the lung. The only secondary effect is the dilatation of the few air spaces that directly abut on the pigmented connective tissues. Such emphysema never involves other parts of the lung and is too restricted in extent to have functional significance.

Gross appearances are determined largely by the color of the inhaled dust. If it has no color, no abnormality may be detectible. If in masses it appears black, the diagnosis will probably be "anthracosis" in the absence of a history of exposure to a specific kind of mineral; really it makes little difference. The pleural surface of the lung is flecked with focal and linear deposits of pigment. The cut surface shows the linear collections in the septums between lobules, the thin streaks along branches of the pulmonary arteries and the rounded flecks scattered here and there which a lens identifies as perivascular accumulations about cross sections of arterioles. The air spaces are always visible in the colored areas, a feature which distinguishes the benign pneumoconiosis from all silicotic reactions. Both the intrapulmonary and the mediastinal lymphoid tissue stand out in sharp contrast by reason of their color. In extreme cases the pigmentation is diffuse and the entire pleural and cut surface of the lung may be black. But in no case is there enough reaction to be detected by palpation or gross inspection.

The shadows cast by such changes on a roentgenogram tend to exaggerate their importance. Except in the most advanced cases the pattern is merely one of exaggeration of the normal lung markings. Since most of the latter are due to the blood vessels, their shadows become heavier and the finer branches are visualized when they are thickened by a sheath of dust and chronic inflammatory reaction. In advanced cases the film may present a reticulated appearance due to the thickening of peripheral arterial twigs and the interlobular septums. The diffuse haziness observed in certain cases may be caused by the presence of great numbers of phagocytes scattered throughout the air spaces. Enough of them in superimposed planes of tissue will intercept some of the x-rays and register a haze on the film.

Since the blood vessels may be thickened from causes other than deposits of dust in their outer coats and since such thickening becomes increasingly frequent with advancing age,¹⁶ there is a great possibility of error in ascribing the exaggerated linear markings seen in a film to occupational factors. In older persons particularly one must beware of diagnosing benign nonspecific pneumoconiosis from a roentgenogram and a history of exposure to dust.

It is hard to imagine that pulmonary symptoms or disability could be produced by reactions of this character. There is generally no involvement of the alveolar walls at all. While in advanced cases there may be a little emphysema, it is confined to only a few air spaces immediately about the pigmented connective tissues of the lung. Even in extreme cases presenting

diffuse pigmentation the lung is still elastic and the respiratory membranes show no abnormality. If symptoms are associated with such reactions they are in all probability due to causes outside the lungs.

As far as can be learned from statistical and experimental evidence, the dusts other than free silica are not responsible for alteration of natural susceptibility to tuberculous infection. There is no proof that their inhalation increases the probability of infection with other organisms. In some of the dusty trades, investigation is disclosing that other factors than the dust are responsible for pulmonary infection.

Scars or imperfectly healed infections in the lungs of persons exposed to these inert or practically inert minerals are sometimes a cause of confusion. They attract and retain abnormal quantities of inhaled dust particles and it is possible, though not yet proved, that such deposits may maintain a preestablished chronic inflammatory reaction. Hence there may be less contraction and less tendency for the area of disease to disappear. Such an outcome is not inevitable, but many more cases will have to be followed in serial roentgenograms before its frequency is established.

Much more puzzling are the patients with obvious fibrosis whose history records only exposure to inert minerals. In most of these instances a review of the facts and a chemical examination of the tissues will disclose that there has been free silica either in the last or in previous exposures. An apparently comprehensive occupational history and the histologic evidence of a single autopsy specimen does not warrant the inference that a mineral other than free silica has caused the fibrosis. Quartz dust masquerades in unsuspected places where much ingenuity may be needed to detect it.

SILICOSIS

Initial Phase.—As already intimated, silicosis begins like the reaction to any other particulate dust, but the peculiar properties of free silica are responsible for subsequent modifications of the standard pattern. Migratory phagocytes concentrate silica in and about the lymphatic system of the lungs. The toxic particles, directly or indirectly through the released lipids, stimulate connective tissue cells in their immediate vicinity and proliferation ensues. The ultimate result is a nodule composed of connective tissue whose fibers are characteristically modified by the effect of the silica. The location of these nodules, situated in the immediate vicinity of the lymphatic trunks, impedes the free flow of lymph. Such a development of microscopic silicotic nodules in the tracheobronchial lymph nodes and intrapulmonary lymphoid tissues constitutes the primary phase of silicosis.

Grossly these early nodular lesions are invisible or recognizable only with a magnifying glass. Usually there is enough carbon or other colored dust inhaled with the silica to produce the linear and focal pigmentation previously described for inert nonspecific pneumoconiosis. Obviously a roentgenogram of such a lung will reveal the shadows of the perivascular deposits but not those of the nodular lesions that are too small to be seen without a microscope.

A history of exposure to a dust rich in free silica with a roentgenogram showing only exaggeration of the linear lung markings presents a problem in diagnosis. I myself believe that if other causes can be eliminated the case should be classified as a benign nonspecific pneumoconiosis, for there is nothing pathognomonic about the film and there is at least only one

chance in four that the disease will subsequently progress to nodulation. Others will argue that the history should be given more weight, and they would call such cases presilicotic.

If silicosis in this early state is not definitely diagnosable during life, has it any significance? Will it progress? Does it increase susceptibility to tuberculosis? The probabilities of progression to a stage of generalized nodulation are slight if the exposure should be interrupted at this stage. This is not necessarily true in the case of a worker such as a sandblaster whose exposure has been heavy and who has attained the stage of linear exaggeration rapidly. With ordinary exposures, however, there would not be enough silica accumulated in the air spaces to produce fresh nodules if no more dust were inhaled. With regard to susceptibility to tuberculosis, statistics on groups of men exposed to relatively high concentrations of silica show a slightly higher incidence of this infection in those with exaggerated linear markings than in those with no visible evidence of reaction to dust. The odds are against a silicotic origin in an individual case, but it could not be proved that silica was not a factor, particularly when atmospheric concentrations of this mineral may have been high.

If there is no probability of progression or no increase in susceptibility to tuberculosis, does early silicosis of this degree have any influence on the body? The only effect thus far discovered is the increased probability that continued exposure to silica dust will ultimately result in more advanced stages of silicosis.

The latter raises problems of administration, the answers to which depend on local conditions and the status of the subject. If the individual is young and linear exaggeration has developed quite rapidly in an environment heavily polluted with free silica dust, he should probably be transferred to some other position. If he is older and serial roentgenograms have shown that such changes have been present for a long time, he can unquestionably remain where he is, especially when an enlightened management is making every effort to reduce the concentration of dust in the working atmosphere. His roentgenographic changes may be due to other causes and hence will not progress because of these conditions.

At this stage of the disease there is no disability or any limitation of respiratory function because the lesions do not encroach on those portions of the lung in which respiration occurs. If physical examination discloses evidence of disability, the cause must be found outside the lungs.

Discrete Nodulation of Classic Silicosis.—After enough silicotic reaction has developed in the lymphoid tissue to retard the flow of lymph, fresh increments of inhaled silica are not as readily removed from the pulmonary air spaces. The phagocytes still ingest particles and migrate with them over the surface of the alveolar lining. Unexplained conditions in the lymphatics (possibly increased lymph pressures) now seem to prevent the cells from entering the vessels. As a matter of observation, most of them collect in groups scattered here and there on the walls of the air spaces. Again the high local concentration of silica results in proliferation of connective tissue cells. Parenchymatous nodules now develop, which ultimately attain a diameter of 3 or 4 mm. They are characterized by the sharp definition of their borders, by their uniform composition of hyaline collagen fibers arranged either

in concentric laminas or in coarse basket weave and by their regular distribution throughout all parts of both lungs. Certain variations are encountered, but these do not cause difficulties in diagnosis. The centers of young nodules may be necrotic when the disease evolves rapidly. Peripheral accumulations of non-siliceous dusts may cause a fringe of more cellular connective tissue that more or less modifies the usual sharpness of the border. The costophrenic portions of the lungs may contain no nodules owing to the development of emphysema in these areas subsequent to the contraction of the many fibrous foci in other parts of the lung. In the early case the tracheobronchial lymph nodes are enlarged, but as the scar tissue contracts they shrink and become exceedingly hard.

The shadows of these larger nodules uniformly distributed throughout the parenchyma of both lungs form a characteristic roentgenographic pattern. When associated with a history of adequate exposure to silica dust and an absence of any very marked physical signs, such a film constitutes an adequate basis for the diagnosis of silicosis. Clinicians generally classify cases of silicosis in three stages, defined by the number and size of the nodular shadows. In stage 1 the linear markings are markedly exaggerated and the nodulation is barely visible; in stage 2 the linear shadows are obscured and each nodule is from 2 to 3 mm. in diameter; in stage 3 the nodules measure from 3 to 6 mm., are less well defined and show a tendency to confluence in certain areas. There is generally a suspicion of associated infection in films interpreted as stage 3.

The clinical significance of generalized discrete silicotic nodulation is not nearly as great as inspection of the film might indicate. Roentgenographic surveys always reveal many cases which have developed entirely unsuspected by the subjects, who have continued to perform their habitual work with no symptoms of respiratory embarrassment. Only shortness of breath on sudden and unusual exertion demonstrates that the respiratory reserve has been reduced. In other words, there is still so much uninvolved lung tissue that normal respiration is unimpaired. Persons with nonclinical silicosis are not disabled and from a medical point of view are employable. Since they are usually skilled by virtue of long experience, the management would generally prefer to keep them at work. However, liability for compensation has complicated the picture and has been responsible for a lamentable rejection of many able workmen.

The nodular stage of silicosis is associated with a definite increase in susceptibility to tuberculosis. This is attested by the old South African figures, which showed tuberculosis of the lungs in 75 per cent of the silicotic miners who died. In the Saranac Laboratory autopsy series active tuberculosis was present in 65 per cent of the lungs of persons exposed to free silica dust and in only 15 per cent of those working in other dusts. Official figures from the Factory Department of the British Home Office¹⁷ disclosed evidence of tuberculosis in 59.4 per cent of the autopsies on silicotic subjects.

The infection may develop as a result of reactivation of a preexisting latent tuberculous focus, but opinion today is unanimous that new infections from without are a more common cause. A contact with the tubercle bacillus, which in normal subjects would perhaps be

quite harmless, is apt, in the silicotic lung, to result in chronic progressive infection. Obviously such contacts cannot occur unless there are open cases of tuberculosis in the locality. In areas in which general living conditions have improved and routine antituberculosis hygienic measures have been put in practice the tuberculosis rate has fallen, among the silicotic as well as among the other members of the community.

The case for nontuberculous infections is not so clearly documented and today it would be well to turn back to Collis's Milroy Lecture of 1915,¹⁸ in which he took great pains to show that pneumonia is relatively uncommon with silicosis though prevalent with "the pneumoconioses that cause bronchitis." Other statistics were published subsequently, however, that showed high frequencies of pneumonia in different dusty trades, and autopsies on silicotic subjects demonstrated the common occurrence of massive areas of fibrosis which closely simulated the end result of an organized pneumonia. Most observers came to believe that the same mechanisms which increased susceptibility to tuberculosis also favored the growth of pneumococci and other bacteria. Thoughtlessly silica was accepted as the common etiologic factor.

But new investigations of silica industries showed that excessive pneumonia rates did not prevail in all of them. Then the importance of exposure to extremes of temperature, humidity and the like assumed proper significance in the silica industries as in others. In mining groups it was shown that the pneumonia rate dropped to approximately that of the local community when the change house was moved to the head of the shaft so that the sweaty, overheated miner no longer had to expose himself to winter weather on coming to the surface. Similarly it is now believed that in the foundry the influence of sudden changes of temperature is much greater than the silica dust, to which only a few of the employees are exposed in dangerous concentrations. In many modern mining areas the incidence of pneumonia is no higher than that in the general population; and the course of the disease when it does develop is usually normal.¹⁹

Pathologic material uncontrolled by a knowledge of general clinical experience may be misleading, owing to selection of cases submitted for examination. It may well be true that some of the massive conglomerate foci seen in lungs are the result of organized pneumonia, but serial roentgenograms of certain silicotic groups make it appear doubtful whether organization is the common outcome.

Experiments by Vorwald, Delahant and Dworski²⁰ show that in rabbits silicosis alters in no way susceptibility to type III pneumococcus or the course of the resultant pneumonia. It is anticipated that similar tests will be made with other types of this organism.

Until accurate statistics based on reliable clinical and bacteriologic data for pneumonias of different origins become available, it would be unwise to generalize. At the present time, however, American experience does not seem to indicate that silicosis has an appreciably unfavorable influence on lobar pneumonia. Possibly infections due to organisms outside the pneumococcus group are in a different category.

Rapidly Developing Silicosis.—Whereas most cases of silicosis require at least from three to six and more often from ten to twelve years of exposure for their development, there are isolated industries in which exposures of from twenty to twenty-four months have produced a modified form of the disease. Under conditions that liberate excessive quantities of exceedingly fine pure silica the ordinary protective mechanisms fail to cope with the situation and an unusual kind of reaction develops. The initial phase of lymphatic involvement is lacking. The overwhelming deposits of silica seem to stimulate connective tissues in every part of the lung at the same time, and as a consequence the alveolar walls become thickened and nodules of microscopic proportions develop throughout the pulmonary framework. The air spaces are filled with actively proliferating phagocytes. Irvine²¹ has aptly described the picture as a "dust pneumonia."

Gross examination reveals no nodules visible to the naked eye; there is merely a generalized partial consolidation of the lungs. All the postmortem specimens that I²² have seen have been complicated by infection which completed the solidification of the involved areas. Because the nodules are too small to be seen without a microscope they do not cast discrete shadows on a roentgenogram. Except when infection complicates the picture, the film generally shows little but a heavy diffuse haze because most of the air spaces contain enough air to permit the passage of some of the x-rays. The diagnosis in these cases rests not on the film but on the presence of extreme dyspnea in a case in which other causes have been eliminated and on the history of an exposure to excessive quantities of exceedingly fine and pure free silica. This diagnosis is never warranted except in the case of unusually severe exposures such as those in unprotected sandblasting or in drilling pure quartz without the ventilation found in ordinary mining practice.

Most of the fatal cases terminate in tuberculosis, as indicated by Middleton's²³ summary of English experience. Foci of necrosis produced by the excessive concentration of fine silica in the microscopic nodules throughout the lungs furnish the most favorable medium conceivable for the growth of the bacilli. A few patients have succumbed to nontuberculous bronchopneumonias, and very rarely it is possible that the silicosis itself may cause death. However, it should always be remembered that evidences of infection are not uniformly distributed and may be hard to distinguish on gross examination of a lung heavily involved with such a reaction to dust. Review of a few small sections in one of Chapman's²⁴ "soap powder cases" failed to disclose evidence of tuberculosis, but so little tissue was available that the possibility of localized infection could not be excluded.

Modified Silicosis.—When the atmospheric dust is composed of a mixture of particles of free silica with those of other minerals such as coal, iron and various silicates the characteristic nodular reaction is modified in varying degrees. When the dust contains enough free silica, nodular fibrosis develops in the pulmonary

parenchyma although the collagen may not show its characteristic hyaline, laminated appearance. The other minerals in the dust tend to be deposited in the interlobular septums and walls of arteries as they would in benign nonspecific pneumoconiosis, but they also collect around the margins of the parenchymatous nodules. The result is a combination of nonspecific pneumoconiosis and silicosis with the specific lesions of each modified by the presence of another type of dust. The linear perilymphatic deposits are heavier and tend to be fibrous; the nodules are larger and lack definition because of fringes of cellular connective tissue. Frequently projections from the nodules are continuous with chronic inflammation about vessels and septums. Reaction about adjacent nodules may replace considerable numbers of air spaces, giving rise to a small conglomerate focus. However, patent air spaces are always present in the involved area. The fibrosis is never of the massive obliterative type to be described later, in which the tissue is uniformly hard and rubber-like in consistency.

Generally the roentgenologist does not attempt to differentiate between these modified forms of silicosis and those produced by purer silica. In occasional extreme cases, however, the nodular shadows may lack their characteristic definition and uniformity in size, the vascular markings will be unusually heavy and there may be a background of more or less uniform reticulation.

Susceptibility to tuberculosis may be more or less favorably modified in these cases. In siderosilicosis due to hematite, tuberculous infection in both man and animals progresses for a time and then in many cases heals with the formation of masses of scar tissue. The same is apparently true of anthracosilicosis, which often requires prolonged search to discover evidence of the tuberculous element in the healed focus. In granite silicosis, tuberculous infection is much more apt to progress and terminate in cavity formation with disseminated infectious lesions.

Since most industrial dusts are mixtures, modifications of the classic picture of pure silicosis are the rule rather than the exception. It cannot be too strongly emphasized that both the pathologic and the clinical manifestations of silicosis in different industries are not identical in all details. Observations that are perfectly valid for anthracosilicosis may be inapplicable to miners of other hard rock, granite cutters' or porcelain workers.

Massive Conglomerate Fibrosis.—This pathologic feature of the disease is the common cause of most of the disability in silicotic subjects. Unfortunately it presents vexatious problems in diagnosis and administrative treatment. During life it may be difficult to differentiate it from the simple conglomerations just described under modified silicosis. In this country and in South Africa most observers think that massive conglomerate fibrosis is due largely to associated infection. In recent years I have come to feel that a third essential factor may be the presence of minerals other than free silica. At the present time it is impossible to classify all areas of conglomerate fibrosis on an etiologic basis. Microscopic examination reveals an element of tuberculosis in 60 per cent of the cases; in the remainder this feature is either absent or escapes detection because it is obscured by the silicotic fibrosis. Although most or perhaps all of these massive fibrous lesions may have developed on a background of tuberculosis, the

problem is to recognize the ones in which the infection is still active. For them some form of treatment is indicated. No treatment in use today is ideal, for all of them tend to promote healing by fibrosis and it is the scar tissue that causes the disabling dyspnea.

Names were coined by the Miners Phthisis Medical Bureau of South Africa to indicate reciprocal relationships between silicosis and tuberculosis in these chronic forms of the disease. "Tuberculosilicosis is the modification produced in silicotic lesions by a chronic tuberculous infection." Here the dust factor is dominant. "Silicotuberculosis," on the other hand, is a clinical term used to indicate that the infectious element is more prominent. On the suggestion of Dr. L. G. Irvine, chairman of the bureau, the last International Silicosis Conference in Geneva adopted the pathologic term "tuberculosilicosis" as the standard one to describe this specific chronic lesion. It is not applicable to every manifestation of tuberculosis in the silicotic lung. When the infection develops typically, as it does in nonsilicotic subjects, the diagnosis should be "silicosis with tuberculosis." Such cases are rare, however.

The anatomic picture of massive conglomerate fibrosis is variable, although there are certain features that characterize all such lesions. The involved area is hard and rubber-like, is blue-black or gray-black, has rather sharply defined borders and is practically always associated with high grade compensatory emphysema. If the area of involvement extends to the surface of the lung there is always chronic fibrous pleurisy with adhesions. Most cases occur in organs showing a background of generalized discrete nodulation, but there are some in which this diagnostic feature is lacking. In the latter case it is possible that contraction of the mass has drawn most of the original nodules into its orbit and that the more peripheral portions of the organ have subsequently been distended by emphysema.

The distribution and extent of the fibrosis varies. The massive scars occur most often in the upper part of one or both lungs. Some radiate from the hilus; some assume the form of wedges with their bases on the pleura; others grow as tumor-like masses in the depths of the lung. They may involve the whole of a lobe and even extend across an obliterated interlobar fissure.

The cut surface of the conglomerate focus generally shows a more or less well defined nodular structure, but at times this is recognizable only with a magnifying glass. Some show central areas of caseation and cavity formation indicative of their tuberculous origin; others are traversed by irregular slitlike openings filled with inky fluid. The latter have no well defined walls and are not differentiated by color from the surrounding fibrosis.

Microscopic sections reveal nodules embedded in a matrix of heavily pigmented hyaline fibrous tissue that replaces practically all normal pulmonary structures. Blood vessels show high grade obliterative endarteritis and often their lumens are filled with dust-containing connective tissue. The larger bronchi are compressed and distorted. When patent, they present advanced chronic inflammatory changes. Tuberculous reaction may be obvious in widespread caseation, but in cases in which the infection has healed it has sometimes been necessary to search over 200 square centimeters of section to discover isolated noncaseous tubercles. In a few cases even this evidence is lacking, but clumps of acid-fast bacilli without cellular reaction are found in areas

of softening. Guinea pig inoculation has supplied proof that the organisms are tubercle bacilli. Examination of the black slitlike cavities has generally revealed no suggestion of tubercle and these cavities have been interpreted as areas of anemic necrosis resulting from the obliterative endarteritis.

In view of the difficulties of diagnosis it would appear unwise to draw any conclusions as to the frequency of nontuberculous massive conglomerate fibrosis.

The shadows of such changes on the roentgenogram offer an easier problem in diagnosis when they occur on a background of generalized nodulation. When this is lacking even the silicotic nature of the disease may be in doubt. Stereoscopic films may permit visualization of discrete nodules otherwise obscured. Overexposed films may bring out tuberculous cavities in the midst of massive shadows, but often none can be seen. The behavior of the shadows in serial examinations over periods of years is perhaps the most reliable index of activity of the process.

The clinical manifestations in many of these cases may likewise be confusing. Often severe dyspnea is the only prominent symptom. Perhaps there has been no loss of weight. The sputum may be repeatedly negative or on rare occasions prove positive by culture or guinea pig inoculation, but if followed long enough the infection in many of these cases will become manifest. Toxic symptoms then suggest tuberculosis; bacilli are constantly present in the sputum; roentgenograms may reveal cavity formation and more rapid extension of the massive lesion. When this is the case death from tuberculosis is the outcome, but the individual in whom the infection has completely healed succumbs to other causes.

Cardiac Involvement.—The question as to the relationship between silicosis and disease of the heart is still debated. Observers primarily interested in silicosis who are following the course of the disease in groups of employed workmen are unanimous in their opinion that cardiac complications are not unusually common. They admit that some silicotic patients exhibit symptoms referable to the heart but point out that the age group in which silicosis develops is also the one in which arteriosclerosis and myocarditis are general. The clinician whose experience is limited to the general hospital, on the other hand, is confronted with a selected group of silicotic subjects. These men have applied for hospitalization because they are sick and often about to die; those who are obviously tuberculous may be transferred to sanatoriums. Thus the internist is naturally impressed by the high proportion of cardiac conditions among his silicotic patients. The pathologist's views are likewise colored by the source of his material. Cardiac complications are rare in able-bodied workmen killed by accidents, but they are not at all exceptional in the older men who die in hospitals at the age of 55 or 60 years. Furthermore, both clinician and pathologist may form unusual concepts of the disease if their material is drawn from a single industry. For example, the anthracosilicosis of the hard coal miners is especially prone to manifest itself as massive conglomerate fibrosis, and it is quite probable that such disease may cause more cardiac complications than the discrete nodulation of sand pulverizing or some other kind of mining.

Cor pulmonale is primarily a disease of the right side of the heart resulting from obstruction to the circulation in the lung. One of the most common

causes of such obstruction is high grade emphysema. Silicosis of the massive conglomerate type is liable to produce such emphysema. No one doubts that many patients with long-standing silicosis complicated by conglomerate lesions caused by associated tuberculosis finally die of congestive heart failure. But the same is also true of patients with uncomplicated tuberculosis, and yet one rarely speaks of this infection as a common cause of "heart disease." Personal experience and the reports from the literature have convinced me that in most fatal cases of silicosis the heart is already damaged by arteriosclerosis or other causes and that the presence of a conglomerate area of fibrosis with emphysema merely adds to its burden. At the autopsy table hypertrophy of the right side of the heart without arteriosclerosis and even greater involvement of the opposite side is a rarity. Clinically no one has ever demonstrated evidence of increasing strain on the right side of the heart as the successive phases of simple discrete nodulation make their appearance. Even in the case of massive conglomerate fibrosis cardiac symptoms are relatively late manifestations. Further clinical and pathologic studies will be valuable as far as they differentiate between the types of pulmonary lesions that are alleged to have affected the condition of the heart muscle.

Carcinoma of the Lungs and Silicosis.—General interest in the subject of pulmonary cancer has been responsible for special effort in securing autopsies in such cases. The discovery of coexistent silicosis or even a benign nonspecific pneumoconiosis has led to the deduction of causal relationships that are not supported by statistical evidence. Vorwald and Karr²⁵ collected from the literature the results of roentgenographic examinations of 57,362 persons at work in industrial plants creating dust of various kinds. Although the group contained 12,206 with silicosis, there were only three cases of cancer of the lung. In the Saranac Laboratory surveys of five different industries, films of 15,587 individuals were reviewed with the discovery of 1,357 cases of silicosis. In the total group there were only three cases of pulmonary cancer, one in a silicotic subject and two in nonsilicotic subjects. The authors' most impressive autopsy statistics were quoted from the 1930 Report of the Miners' Phtisis Medical Bureau of South Africa. This official publication cites postmortem figures on 4,510 adult males including 3,117 European miners and 1,393 European males with no underground exposure. The frequency of pulmonary carcinoma was as follows: 1,393 European males, no underground work, 0.93 per cent; 1,679 European miners, no silicosis, 0.71 per cent, and 1,438 European miners with silicosis, 0.70 per cent.

... should be less likely to initiate a ... of epithelium than the tubercle bacillus. The latter not infrequently does cause metaplasia of bronchial epithelium and sometimes carcinoma eventually results. In uncomplicated silicosis, however, there is no effect on the epithelial elements that give rise to cancer. The silica stimulates only the fibroblast or connective tissue cell. If anything there should be an excess of pulmonary sarcomas, but these have not been reported.

In spite of the occasional coexistence of silicosis and primary carcinoma of the lung indicated by published

autopsy reports, it is felt quite definitely that the silica has no etiologic significance. The only dusts known to cause pulmonary carcinoma are those of the radioactive ores in Schneeberg.²⁶ Possibly, as Campbell's²⁷ experiments have suggested, the tar in road dust may also be significant; but this awaits proof.

ASBESTOSIS

It will be recalled that protective mechanisms of the upper respiratory tract appear to be less effective against fibrosis than against particulate foreign bodies and that mobile phagocytes do not remove long fibers from the pulmonary air spaces. As a consequence the greatest accumulation of inhaled asbestos fibers occurs in the lumen of the respiratory bronchiole, the point at which they first come to rest. Almost none are found in the areolar tissues about lymphatic trunks or in the lymphoid tissues inside or outside the lungs. Reasons for believing that the stimulus from inhaled asbestos may be mechanical rather than chemical have been discussed in the first paper on etiology.⁴

Microscopic Appearance.—As long as asbestos fibers continue to be inhaled, scar tissue develops as a gradually thickening sleeve about the respiratory bronchioles. Either because the bore or the tube is smoothed out by the obliteration of the lateral alveoli or because of changes in the lining epithelium, subsequently inhaled fibers then pass on into the alveolar ducts. Here a similar sleeve of fibrosis develops, and this formerly irregular tube likewise permits fibers to pass farther into the lungs. Reaction in the walls of the terminal air spaces ultimately results in a localized patch of obliterative fibrosis of the parenchyma of the lung.

A random microscopic section through an area of fibrosis does not reveal a uniform obliteration of every air space. Here and there are many that still contain air; some are of normal size, some are compressed and many are greatly dilated. These patent air spaces are apparently supplied by other bronchioles that did not happen to be involved in the primary fibrosis. Their intrusion into the area of scar formation is easily understood on reference to Miller's²⁸ models of the terminal branches of the bronchial tree. His diagrams show that the terminal air spaces of different bronchial systems are packed together in such a manner that a single section will contain alveoli given off from widely separated bronchi. Many writers have described this condition as bronchiectasis, but emphysema would seem to be a more apt term as the larger bronchi and bronchioles are never involved.

The scar tissue of asbestosis is in no way peculiar. Unlike that of silicosis, it fails to show a characteristic hyaline swelling of the collagenous fibers. Its arrangement is usually diffuse rather than nodular, although occasional cases such as those reported by Lynch and Smith²⁹ may present a few nodules. Their presence suggests that there may have been an unrecognized contamination of the inhaled dust with free silica.

Because the fibers are not transported, the asbestosis bodies which develop from them will be found very

largely within the scar tissue around bronchioles and the air spaces which they supply. But, as Gloyne³⁰ has pointed out, commercial asbestos usually contains particles of various contaminating minerals. Physiologic mechanisms within the lung are responsible for the sorting out and removal of much of this particulate matter to the pulmonary framework and lymph nodes. There it sets up a nonspecific pneumoconiosis the color and intensity of which depend on the quantity and character of the contaminant. After the development of parenchymatous fibrosis the particulate matter is not removed so readily. Its retention in the patches of reaction due to the asbestos is responsible for the pigmentation seen in advanced cases of asbestosis.

Gross Appearance.—These observations make it easier to appreciate the variable gross picture in asbestosis. The obvious changes consist of patches or strands of dense scar, which are irregular in size, shape and distribution. In advanced cases they are gray or black and included in all of them are thin-walled, dilated air spaces that vary from a few millimeters to a centimeter or more in diameter. Fibrous pleurisy plus a variable amount of pigmentation in the walls of the pulmonary arteries and interlobular septums complete the grosser changes.

More careful inspection, perhaps with the aid of a magnifying glass, demonstrates numerous minute, ill defined patches of fibrosis widely scattered throughout the parenchyma. If they happen to be sufficiently pigmented by minerals other than asbestos, such foci will stand out sharply like those illustrated in color in Gloyne's³⁰ article, but only one of the twenty-eight cases in my collection even approximates this picture. The borders of these lesions invariably lack the sharp definition of the silicotic nodule. Here and there the plane of section will cut one of these areas in such a manner that the thick-walled bronchiole with its peripheral fan of fibrosis is clearly recognizable. The lens demonstrates the presence of dilated air spaces within each fibrous area if these are not already large enough to be seen with the naked eye. Elsewhere the air spaces will be visible, but their walls are much less prominent. The patches of fine fibrosis, scattered throughout the lung, are not sufficiently large or dense to be palpated individually, but they increase the general consistency of the organ and limit its crepitation.

It is now felt that the fine, diffuse fibrosis with emphysematous dilatation of included air spaces constitutes the characteristic feature of asbestosis. Whether the grosser patches of scar tissue represent merely an intensification of the same process in localized areas or whether they are due to reaction to dust in the scars of healed infection is not altogether clear. Sometimes they occur as a thin zone beneath and paralleling the pleura, an arrangement hardly suggestive of infection; at others, more localized patches of scar simulate old foci of infection. The chronic pleurisy is probably not a reliable index of infection, as it seems to occur whenever subpleural air spaces are involved. The thickening of blood vessels and interlobular septums are variable accompaniments due to accidental contaminants in the inhaled dust. The same is true of reaction in the tracheobronchial nodes.

Roentgenograms.—Compared with the microscopic appearances, the roentgenographic shadows of early or even moderately advanced asbestosis are surprisingly

slight: A faint haziness throughout the lower lung fields together with more or less evidence of chronic pleurisy are the only unusual features of these cases. Pleural manifestations may be limited to visualization of the transverse fissure of the right lung. There is also more or less exaggeration of the linear markings, but the specificity of this reaction is questionable. As shown by Gardner, Durkan, Brumfiel and Sampson,³¹ in cement workers the frequency of such exaggeration tends to increase more with age than with dust exposure. Dreesen, DallaValle, Edwards, Miller and Sayers³¹ concurred but found more of this type of reaction in old asbestos operators than in persons not exposed to dust and less than in those of the same age exposed to kaolin dust. As suggested in the section on pathology, linear exaggeration is probably an accidental accompaniment of asbestosis and in my opinion should not be considered as an index of early reaction to the fibrous silicates.

In far advanced cases there is a heavier diffuse shadow throughout the lung fields, whose appearance has been compared to that of ground glass. Its uniformly fine granular texture is undoubtedly due to the superimposed shadows of the small patches of fibrosis in the parenchyma alternating with patches of radio-translucent patent air spaces. The very advanced case may show in addition many small fleck-like shadows on the generally hazy background. The shadows never present the sharp definition of silicotic nodulation. The so-called porcupine heart, said to characterize advanced asbestosis, is manifested by heavy linear shadows that radiate into the lung fields from the surface of the heart. They may be cast by pleuropericardial adhesions.

Clinical Symptoms.—The symptoms most commonly reported are an irritative cough and dyspnea; some would also include weakness and chest pains. A dusky color suggesting cyanosis, clubbed fingers and blood streaked sputum are symptoms of advanced disease whose frequency apparently varies in different locations. Dreesen and his associates³¹ find that cough and dyspnea are by far the most common symptoms and that their frequency increases with the intensity of change visualized in the roentgenogram. Of the patients with far advanced cases 82 per cent had both; of those with moderately advanced cases 72 per cent complained of cough and 68 per cent were short of breath. Since the dyspnea must be due largely to associated emphysema, it is quite conceivable that this symptom should appear early and explain the incidence of dyspnea in 33 per cent of persons whose films showed only second degree linear exaggeration. These observers discovered no greater frequency of cardiac involvement than in industrial groups in general. Others have reached the opposite conclusion, but here again allowances must be made for the source of their material. Theoretically there would seem to be greater reason to suspect cardiac involvement in cases of simple asbestosis than in simple silicosis. Further study is needed to elucidate this point.

Merewether,³² who gave a classic description of this disease, reports that a minimum of seven years' and more commonly eleven years' exposure to high concentrations of asbestos dust was necessary to produce a serious degree of reaction in the English plants. In this country Dreesen and his associates³¹ found the

31. Dreesen, W. C.; DallaValle, J. M.; Edwards, T. I.; Miller, J. W. and Sayers, R. R.: *A Study of Asbestosis in the Asbestos Textile Industry*, U. S. Pub. Health Bull. 241, 1938.

minimum duration somewhere between five and nine years, depending on the character and concentration of the dust inhaled. At this time 27 per cent of exposed workers were involved, and among those with more than fifteen years of employment the percentage rose to 60.

The question of progression after cessation of exposure has had various answers. Merewether¹⁷ and Ellman³² both believe that asbestosis invariably progresses to a fatal termination once enough fiber has been entrapped in the lungs. The former reports one case in which a mattress maker died eight years after ceasing an employment of four years and five months. An autopsy revealed far advanced ashestosis, but unfortunately there had been no films to indicate the extent of the progression. Mills³³ reported a case in which a man died of congestive heart failure approximately thirty-two years after an intermittent exposure of three years. I was privileged to study sections from this patient, but if there had been any progression it had not involved much of the lungs. There were a few small patches of pulmonary fibrosis containing rare atypical asbestosis bodies. Lanza³⁴ is of the opinion that "it is by no means certain that asbestosis progresses as does silicosis after withdrawal from dust exposure." In experimental asbestosis of guinea pigs the pulmonary reaction retrogresses after removal from the dust rooms. On the basis of mechanical injury there should be no progression, for the rounded surfaces of the asbestosis body would produce less trauma than the rough ends of the freshly inhaled fibers.

Diagnosis depends on a history of adequate exposure, evidence of characteristic roentgenographic changes and the clinical picture. Asbestosis bodies in the sputum are confirmatory but alone they do not indicate disease. Any one may inhale a few asbestos fibers, but their number is too small to be significant. In routine examination of sections of the lung I have discovered occasional asbestosis bodies in a dozen or more cases in which no history of exposure to this dust could be obtained.

Susceptibility to pulmonary infection in asbestosis is not nearly as well defined as in the case of silicosis. English writers like Merewether,¹⁷ Ellman³² and Gloyne³⁰ are impressed by the high incidence of tuberculosis among the disabled patients and those who died. American statistics based on surveys of employees in different plants, on the other hand, show relatively little tuberculosis. Dreesen and his associates³¹ reported only two cases of active infection among 541 persons exposed in the asbestos fabricating plants of North Carolina. However, some 150 employees had been discharged fifteen months previously. Of the latter, seventy-one were examined by Shull,³⁵ who reported eight cases of tuberculosis, only two of which were active at the time. In the entire group "the degree of infiltration was only slight to moderately advanced, and one or both upper lobes were involved." He found that thirty-five of the patients had moderately advanced ashestosis, of whom two subsequently died or were dying of tuberculosis, twenty had far advanced ashestosis with two more cases of tuberculosis. This would make a total incidence of 7.2 per cent for the dis-

charged group. The figure for the entire group of employed and discharged subjects cannot be computed as so many of the latter have not been traced. McPheeters,³⁶ among 210 employees from the same district, found an incidence of active tuberculosis of 2.8 per cent. In Pennsylvania, Fulton, Dooly, Matthews and Houtz³⁷ discovered two cases of healed tuberculosis among fourteen persons with asbestosis. In 1936 Lanza³⁴ summarized all the available evidence and failed to find convincing evidence of a great excess of tuberculosis.

The autopsy statistics are more suggestive. Egbert³⁸ reviewed the cases reported up to 1935 and found that six out of twenty-eight showed complicating tuberculosis. Merewether¹⁷ reports an incidence of 35.7 per cent in forty-two fatal English cases. Dreesen and his associates³¹ include autopsy reports in three cases with no tuberculous complications. My own series, which includes twenty-eight specimens, most of which have been previously reported elsewhere, contains nine cases of active chronic tuberculosis. While these autopsies reveal a high incidence of such infection, their number is too small to compensate for the factor of selection. The data from the surveys probably constitute a more reliable index.

In experimental animals asbestos dust³⁹ has nothing like the effect of free silica on associated infection. Like gypsum, iron oxide and other nonsiliceous minerals, asbestos may cause tuberculous infection to progress for a time, but it subsequently heals with a marked tendency to scar formation. The fibrosis from the infection then retains excessive amounts of inhaled asbestos and unusually large patches of scar develop in the pulmonary parenchyma.

The cause of death in the remaining cases has been certified as nontuberculous pneumonia, myocarditis, pulmonary cancer and a miscellany of other conditions.

Tuberculosis may be an unusually frequent cause of death in certain groups of asbestos workers, but at present it seems more probable that nonspecific hygienic factors and general living conditions are responsible. The actual frequencies of nontuberculous infections and primary cancer of the lungs are unknown. One must not be misled by a comparatively small number of postmortem reports.

Effect of Flying on the Ear.—Flying has no significant effect on the external ear, but the middle and inner ear are the source of a great amount of difficulty. The magnitude of the ear problem in aviation may be judged from the fact that pilots suffer more frequently from occupational disturbances of this organ than from all other occupational diseases combined and that it is the most frequent cause of discomfort among passengers on commercial air lines. The conditions of flight which most affect the ear are changes of atmospheric pressure during ascent and descent, noise, and possibly vibration. At the present time the former is increasing in importance as a result of the increased climbing ability of modern aircraft, while the two latter conditions are decreasing in importance as a result of recent advances in aircraft design. *Principles and Practice of Aviation*, G. THE TEACHING OF THE OCCUPATIONAL DISEASES

RUTHERFORD T. JOHNSTONE, M.D.

LOS ANGELES

It is obligatory that education fulfil the requirements born of a changing social and economic philosophy: that it be harmonious with the constantly altering pattern of vocational needs. While the biologic inheritance of a race remains practically unchanged from age to age, education is always relative to some concrete and evolving social situation. Hence the problem of education assumes one form in ancient Athens, yet quite another in twentieth century America. What was adequate in our fathers' time is now inadequate. It is clear, therefore, that any group charged with the task of shaping the educational theory or practice for any people should consider the trends and interests of the society which it serves. Medical education is no exception to this truth. Although usually deliberate, and in this instance dilatory, it has always met each new exigency. Yet the excision of the old and the implantation of the new have ever been fraught with objections from those members of the medical faculty whose vision has reached the "fixed period." Periodically, inevitable inclusions within the curriculum are met with objections from this group, on the basis that the "course is already overcrowded." No doubt roentgenology, orthopedics, psychiatry and other subjects now taught were once confronted with this same opposition.

Today, seeking admission into the sanctum of clinical teaching comes a knock from occupational diseases, and the urgency of the situation demands that the door be opened to them. Many educators and those who practice medicine outside the fence of industry will wonder why this phase of medicine is apparently receiving sudden emphasis. For these, a brief enumeration of the precipitating factors seems appropriate.

THE LEGAL ASPECT

Workmen's compensation was initiated as an experiment but has since become an established institution, now being in effect in all but two states. Originally designed to compensate for "injuries by accident," the first laws excluded disability not traumatic in origin. Today twenty-two states make provision for all or some occupational diseases. Ominous signs indicate their rapid inclusion by the remaining states. After such enactments the responsibility shifts from a few to all physicians. The existing system of consigning the sudden fracture or laceration to the plant or company physician will continue. In such cases the causative factors are rarely in doubt. But the workman with insidious disease will consult his family or neighborhood physician, on whom will be imposed the duty of determining whether the patient's condition is occupational or nonoccupational in origin. In every city, hamlet, mining center or farming district a workman's ill health will become a medicolegal problem. The foundation for the equitable fixation of liability, therefore, rests on diagnosis. It is apparent that the legal recognition of occupational disease has not been paralleled by the medical profession.

THE MEDICAL ASPECT

The etiology of illness has been abundantly augmented within the past few years. Unto the diseases of

commonalty have been added those which find their cause in dusts, fumes, solvents, metals and noxious gases. Since the World War, the pace set by creative genius in the manufacturing of new products and the devising of new processes has resulted in a dizzy multiplication of hazards. The potentialities represented by 32,000 research workers, now engaged in industrial and consulting laboratories, portend annual additions. In Maryland, for instance, 41,000 workmen may be expected to be exposed to carbon monoxide, 32,000 to organic dusts, 30,000 to metallic mineral dusts, 34,000 to substances apt to produce dermatitis and 8,000 to the inhalation of silica dust. Three fourths of the industrial population studied were subjected to exposure to one or more of the forty-three groups of material listed in the survey. These figures, quoted from bulletin 236 of the United States Public Health Service, may be multiplied many times for those states which are larger industrially. Also certain states have hazards not found, or at least not prevalent, in other states, as for example the synthetic nitrate production in Virginia, the rayon industry in Pennsylvania, the petroleum industry in Pennsylvania, California, Oklahoma or Texas, and the mineral mining in the Western states.

THE EXISTING INADEQUATE SERVICE TO INDUSTRY

The situation would not be so grave if it were confined to the larger industries. Efficient medical supervision as to prevention, diagnosis and treatment prevails in the larger corporations. But the small plant or company employing ten, fifty or 100 men lacks such supervision, although the hazards are just as great. The employer is financially unable to maintain his own medical staff and is therefore dependent on the physician next door or around the corner. It is with the training of this physician that medical education must concern itself.

THE BURDEN ON INDUSTRY AND THE INJUSTICE TO WORKMEN RESULTING FROM ERRORS IN DIAGNOSIS

Do the occupational diseases present a diagnostic problem distinct from that of the ordinary ills of life? If the reader is to obtain an adequate conception of the dissimilarity between general medicine and industrial medicine, let him answer the following question, meanwhile tabulating for his own information the data his research discloses: What are the signs and symptoms attributable to the illness allegedly arising from the occupation of a furrier, fumigator, sand blaster, welder, maker of felt hats, abrasive soap maker, cotton sorter or degreaser (textile); from employment with refrigeration, vulcanizing or photography, or from working with rayon, benzene, cement dust, carbon disulfide, carbon tetrachloride, aniline dyes, pottery, chromium or methyl chloride or with solutions used in electroplating, glass etching or dry cleaning? Having listed these signs and symptoms, state whether the illness is apt to be acute and temporary, without sequelae; sudden, with death ensuing or permanent disability resulting; or insidious, with or without permanent disability.

These are but a few of the exposures in the hundreds of occupations which incorporate potentially harmful materials, processes or environments. Does not the preceding questionnaire indicate the changing complexion of medicine?

THE SOLUTION

Occupational diseases can be taught in practically every medical school in this country, beginning next fall. Offhand, such an assertion appears as an overstatement. True, room cannot be made for them in the present curriculum as easily as one sets an extra plate for the unexpected dinner guest. A separate course will eventually obtain only after progressive readjustment. But the subject can be made an active component of the clinical years by including it in the differential diagnosis during the ward walks or dispensary teaching without discommoding the course. To this, certain voices can be heard saying "But we do this now whenever we have an opportunity." That is not sufficient. It is too casual, too occasional, and characterized by dependence on chance. It would be comparable to studying aortic stenosis only when a case happened to come the way of that particular clinic. Accomplishment of purpose will require a planned, supervised system, together with interdepartmental cooperation. Occupational diseases can be added to the curriculum without additional hours, equipment or particular enlargement of the faculty. I am cognizant of the trend away from didactic teaching. In no way does the proposed plan violate that principle.

The first step in the accumulation of suitable clinical material for demonstration should be the creation of a division of occupational diseases in the outpatient department under the direction of a physician. He should be rich in industrial experience, with a strong sense of the possibilities of correlating the instruction of this kind with the programs of other departments, as for example medicine, dermatology, toxicology, traumatic surgery, and preventive medicine and public health. Once established, such a department could quite conceivably form the basis for the formation of a separate discipline in the medical school for instruction in the wider aspects of industrial health, particularly along graduate lines as the need for specialization clarifies, and to provide means for special investigations. It is not necessary for the director to have had teaching experience, nor need he be expected to teach, but he should have ability to organize. In every center such men are available. His first objective should be to gain the cooperation of the plant and industrial physicians of a community who represent a wide variety of industries. In the suggested scheme this group represents the "department of supply." Monthly meetings with the director, at which time material and methods of presentation are discussed, would constitute a seminar from which would flow an exchange of ideas valuable to the department and instructive to this group of plant physicians. This setup having been established, the office of the director becomes, in the parlance of Hollywood, a central casting bureau. In it will be registered the cases on call, and from it the cases will be assigned to the clinic best suited for their study.

A suspected case of lead poisoning admirably serves to emphasize the advantage of this method of linking teaching with industry. In the present system, isolated from the industrial physician's aid, the student, and too often the teacher, is forced to refer to the standard textbooks of medicine. The following quotation is from a recent volume on the "Practice of Medicine": "The diagnosis of lead poisoning rests upon finding the blue line in the gums and the presence of numerous basophilic cells in the blood smear. Absolute confirmation is obtained by detecting lead in the urine or feces."

How misleading! The blue line isn't necessary and is likely to be absent. Basophilic stippling is not pathognomonic, and lead can be detected in the urine and feces of normal persons. Contrast such insufficient information with the suggested manner of study.

A paint sprayer consults his plant physician regarding recently developed gastrointestinal symptoms which the workman feels are due to lead poisoning. Following a "thorough work-up" the plant physician registers this case in the department of occupational diseases. At a designated time, and bearing the necessary data, he appears before the gastrointestinal clinic. After the consideration of history, including occupational exposure, symptoms and physical examination, the possibilities of ulcer, cancer, gallbladder disease, appendicitis, allergy, neurosis and lead colic are discussed. His laboratory reports are then read, interpreted and compared with normal figures for evidences of lead in the blood smear, whole blood and twenty-four hour urine specimens.

By this method the clinician is supplied, without excessive time or effort on his part, with the essentials for a differential diagnosis. In one period the student learns concretely what constitutes a lead exposure, the distinction between normal lead absorption, abnormal absorption and intoxication, and the criteria necessary for diagnosis.

A rash appearing in the cement or rubber worker will be referred to the section on dermatology and anemia in the dry cleaner to the section on hematology; to the tumor clinic will go the patient alleging his cancer is due to industrial exposure; cough, hemoptysis or dyspnea in one engaged in the dusty trades will be studied by the group concerned with pulmonary diseases, as well as by the class in roentgenology for the consideration of pneumoconiosis. These examples are sufficient to illustrate the scheme suggested.

It is anticipated that there will be those who will consider this plan not feasible, since the workman is not a charity patient. Unquestionably there will be objections from a small percentage of patients. But the material is so abundant that out of the mass there is certain to be a sufficient number of patients from whom cooperation will be gained. The average workman is not a malingerer; he is desirous of obtaining a correct diagnosis and appropriate treatment of his case. I have experienced no difficulty in securing his cooperation in any investigation I have undertaken. It is inconceivable that in every teaching center physicians holding positions comparable to those of Drs. Selby of General Motors, Woody of Standard Oil, Cheney of Armour and Company, Hazlett of Westinghouse, Shoudy of Bethlehem Steel, Bartle of the Pennsylvania Railroad and McConaughy of the Aluminum Company of America would not cooperate in such a plan to supply a constant stream of teaching material to the medical school.

CONCLUSION

I entertain no delusion that the plan suggested should be permanent or is without fault. I am obsessed, however, with the belief that action is imperative. Nationwide legislation imposes a medical responsibility that must be met. Until such time as deletion of certain obsolete courses takes place and room is accorded this subject befitting its importance, the plan herein suggested appears workable and obviously supplants the present hit and miss system.

ADEQUATE NUTRITION FOR THE
INDUSTRIAL WORKER

LELA E. BOOHER, PH.D.

WASHINGTON, D. C.

Except for some few special circumstances affecting a minority of the total group, the problem of adequate nutrition for the industrial worker is the nutrition problem of all workers. It is the good fortune of the industrial worker that this is so. The probability that any individual can benefit by each new advance in the science of nutrition and that proper food in adequate quantities can be provided for him depends a great deal on the fundamental similarity in the nutritive needs of individuals.

This is not tantamount to saying that individual variations in nutritive needs can be ignored. Rather, one has to be on guard to find a guiding principle in medicine or nutrition in the maze of physiologic variations encountered in studies of human beings. But isn't it true that the solution of the individual problem in medicine and in nutrition involves starting with a set of rather fundamental general concepts with the avowed purpose of trying to find out the particular degree of variation that needs to be tempered? The boundaries between normal variations and frank derangements in health and nutritive state are indistinct. For this reason the boundaries between the science of medicine and the science of normal nutrition lack real definition. The practical aim of the two sciences, namely to improve the physical welfare of man, is one and the same.

First of all it must be recognized that the term "industrial workers" includes more than $8\frac{1}{2}$ millions of people in this country and many more millions if one looks beyond the borders of this country. Of these $8\frac{1}{2}$ millions of people in the United States who are wage earners in industry, a little more than 20 per cent are women and the rest are men. The range in age covers the whole gamut of the productive years of adult life. If the activities outside of working hours are considered, the range in activity probably encompasses the whole range of activity of humanity. If, therefore, some practical program designed to improve the nutrition of the industrial worker can be arrived at it will certainly be profitable.

ENERGY REQUIREMENTS

In the minds of many persons, industrial work is frequently associated with an extraordinary degree of physical effort, comparable perhaps to that of the athlete in training or of soldiers on a long march. This category includes many workers in the so-called heavy industries, but actually many industrial workers are not called on for heavier physical exertion than the average secretary, housewife, barber or taxi driver. However, the duties of the industrial worker are likelier to be more routinized and monotonous perhaps than the occupations just named. But it would certainly be a mistake to discuss energy requirements of industrial workers in the aggregate.

The task of estimating energy requirements can be greatly simplified by setting the maintenance need for an average man at about 2,400 calories a day and at

about 15 per cent less than this for an average woman. This maintenance allowance presumably meets the energy needs for a person living an ordinary life in a temperate climate without being engaged in manual work. The League's Technical Commission on Nutrition¹ suggests the following additional allowances for muscular activity of adults:

Light work: up to 75 calories per hour of work.

Moderate work: from 75 to 150 calories per hour of work.

Hard work: from 150 to 300 calories per hour of work.

Very hard work: from 300 calories and upward per hour of work.

In assessing the energy requirements, one must not lose sight of the fact that some of the ordinary pursuits of pleasure and relaxation may be hard work in the physiologic sense. Painting and brisk walking are good examples of moderate work. Carpentry, skating, dancing and bicycling are typical examples of hard work. Sawing wood, digging, stone masonry, running and swimming are very hard work in the sense that they require rather enormous rates of energy expenditure. To assess fairly a worker's energy needs, therefore, it is necessary to consider the expenditures of energy beyond the fixed working hours, because chores and sports may affect the need very appreciably.

A great deal has been written about fatigue in industry. Strictly speaking, muscular fatigue connotes a state within the muscle fibers wherein the recovery processes during exercise have not kept pace with the processes of breakdown. An oxygen debt is built up which can be relieved by rest. If the muscle fibers lacked this ability to take on an oxygen debt temporarily, no physical effort of any considerable severity could be made. The term "industrial fatigue," however, is more generally used as referring to the lessened capacity or inclination to do work which results from the previous doing of work of the same kind. Proper nutrition is one of the factors essential to the promotion of maximum efficiency of workers. There are, of course, many other factors involved as well.

Haggard and Greenberg² have reported a distinct rise in muscular efficiency after meals which they associate with an increased utilization of sugar. In their experiments, muscular efficiency followed rather closely the changes in sources of energy as reflected in the respiratory quotient. The body possessed the capacity to do physical work efficiently when the respiratory quotient was at a value between 1.0 and 0.85, while below 0.85 the efficiency was observed to be low, approaching the before breakfast condition. This suggested that when sugar was being used as the source of energy for work the work was less difficult than when fat was being used. It should be mentioned that Haldi and his co-workers³ were unable to confirm these observations, and no rational explanation has been offered to reconcile these two sets of experiments. However, Haggard and Greenberg's original contention appears to be supported by results of its practical application to the productivity of factory and office workers. For several obvious reasons, the feeding of sugar alone to workers at frequent intervals every day would not be a commendable practice; however, there

From the Bureau of Home Economics, United States Department of Agriculture.

Read before the second Annual Congress on Industrial Health, Chicago, Jan. 13, 1940.

is no violation of the principles of good nutrition in the use of more frequent meals if the sum total of food intake is thereby not made excessive and if the requirements of a well balanced diet are met.

These same investigators have described a study of between meal feedings made in a large industrial plant manufacturing rubber footwear. They selected from a series of unit operations that of sewing together (by machine) the canvas parts of the tops of tennis shoes. Rows of operators could take from a conveyor belt, as needed, baskets filled with unassembled tops, sew them together and replace the baskets, together with a slip giving the operator's number. The wage system provided a minimum hourly wage plus an additional sum based on rate of production. The hourly production of the individual operators was recorded from the number of assembled shoe tops returned to the baskets placed on the conveyor. A sustained hourly rate of production was strikingly apparent for operators accustomed to eating food in the third hour of the morning and afternoon working periods (five meals in all) as compared with those eating only two or three meals a day. The productivity of another group of operators accustomed to three meals a day improved very significantly when given in addition light lunches of milk and "angel cake" at the beginning of the third hour of the morning and afternoon working periods. The operators also volunteered the information that they felt less tired on those days when they had five rather than three meals.

Haggard and Greenberg⁴ have recently reported a controlled study of the effects of between meal feedings of bananas or milk and bananas during previously established rest periods on the disposition and absenteeism of a group of 120 clerical workers in a large commercial office. There was a marked decrease in absenteeism among the employees receiving these two daily supplementary lunches. Most of the employees approved of the supplementary food and thought that they became less tired and were kept in better spirits and were more attentive to their work.

These investigators believe that it is entirely possible for persons to be relieved of a feeling of fatigue, irritability and muscular inefficiency by frequent feeding and at the same time to satisfy the requirements for a well balanced diet without overeating. Probably most of those participating in this congress could bear witness to the fact that hunger is associated with weakness, irritability, diminished ability to concentrate and disinclination for sustained work. If a daily diet of the same quantities of a well balanced selection of food eaten in five meals instead of in three meals will make persons happier and more effective, why not? The opposition will cling to two main objections—the stomach needs rest and the habit of three meals a day is firmly entrenched. Well, if one is really honest about it, isn't it the oversized meal that puts the burden on digestion and makes one dull and listless? For the gastric ulcer patient, the invalid and the convalescent, the frequent small meal is very regularly advocated—what about rest for the stomach in these cases? For those who resist change that seems to offer possibilities for betterment merely because it disturbs an established routine, neither science nor reason has an answer. This proffered change in mealtime frequency has enough basis in experimental background to warrant further

trial in practical application as a possible means of promoting the health and cheerfulness and productivity of millions of workers.

PROTEIN REQUIREMENTS

Rose and his co-workers⁵ at the University of Illinois have recently isolated and identified a new amino acid which they named d-threonine. As a result of this discovery it is now possible for the first time to rear animals on diets containing mixtures of known amino acids instead of proteins.

Of the twenty-two or more known amino acids, nine or ten must be considered as indispensable. That is to say, nine or ten cannot be synthesized by the body at all or not at rates sufficient to supply adequately the body's needs for them. The amino acid arginine, for example, can probably be synthesized in considerable amounts in the body but not at a sufficiently rapid rate to support normal growth. Methionine, a sulfur-containing amino acid, is one of the indispensable amino acids, while cystine, a sulfur-containing amino acid prominent in the composition of hair and nails, apparently is not. However, diets low in methionine can be enhanced with respect to their growth-promoting properties by the addition of cystine. It seems, therefore, that methionine is essential for certain bodily functions which cystine cannot satisfy but that in certain other functions cystine can spare methionine.

It is not known at present whether or not a deficiency of each one of the indispensable amino acids in the diet produces a specific syndrome. Specific amino acid deficiencies is one of the new problems awaiting the solution for which the work of Rose and his associates has pointed the way.

The day may not be too far distant when scientists will be able to speak of specific amino acid requirements rather than lumping these all together indeterminately as a protein requirement. It is well recognized that proteins from natural food sources vary widely in their amino acid makeup. Because the proteins from animal sources are richer in many of the essential amino acids than the cereal and vegetable proteins, the former proteins are spoken of as having higher nutritive value. Plant proteins in general are much lower in the indispensable amino acid lysine than animal proteins. It has also been established that higher intakes of lysine are necessary to support normal growth in small animals than of any other of the indispensable amino acids. Because the freely chosen diets of individuals vary so widely in combinations of proteins, it is important to allow a liberal margin of safety on protein intake, hoping thereby to secure adequate amounts of all the essential amino acids. It is also imperative to recommend that milk, meat, eggs, cheese and fish supply a good proportion of the protein allowance. For the average adult it would appear that equal amounts of protein from animal and vegetable sources were a very favorable source-distribution.

Many authorities have accepted a daily allowance of 1 Gm. of protein per kilogram of body weight (or 70 Gm. for a man) as probably representing a reasonable margin of safety for the protein requirements of adults. Other authorities tend to regard this quantity as "not

liberal" at least. Leitch⁶ recently presented a reevaluation of the experimental results dealing with nitrogen balances and concludes that the allowance should be on the order of 80 Gm. per adult daily to provide a 50 per cent margin of safety. McCollum and his co-authors⁷ of the recently revised "Newer Knowledge of Nutrition" place the adult daily allowance for protein at around 110 to 120 Gm.

Another aspect of this question should be mentioned here. Foods rich in protein of the best biologic value are, in the United States, among the more expensive types. Stiebeling and Phipard⁸ have shown that as the wage earners' expenditures for food increase, more money regularly goes toward the purchase of protein-rich foods. Apparently most adult wage earners much prefer a diet that provides around 110 to 120 Gm. of protein daily. It appears to be the cost that deters them when they consume less protein than this. There is very little evidence to indicate from a physiologic standpoint that adults should not consume from 110 to 120 Gm. of protein a day if it pleases them. The idea that high protein intake places an extra burden on the kidneys with resultant injury to their function and structure lacks real justification. There is no indication that the changes in these organs of normal animals fed on diets abnormally high in proteins are anything more than a normal physiologic response to increased functional demands.

The distribution of potential calory foods in most American diets is apportioned with about one eighth of the calory value from protein, one third from fat and the remainder from carbohydrate. If approximately the same relative proportions of these three nutrients are maintained throughout the range of adult requirement for total calories the result will be a very good balance among these three important nutrients; the protein requirement will be adequately met and the worker pleased. The protein, however, should be supplied at all levels of intake in the form of a variety of animal and plant foods in order that all the indispensable amino acids shall be adequately represented.

INORGANIC ELEMENTS

The human body and the foods on which it is dependent contain a wide variety of inorganic elements. Some of the inorganic elements, notably calcium, phosphorus, sodium, potassium, chlorine, iron, magnesium, iodine and sulfur, are present in and required by the body in rather substantial amounts. Besides these, some very small quantities of other elements are essential to normal life processes. The list of recognized essential trace elements is gradually growing in numbers. Many elements, however, have not yet been subjected to a crucial test adequate to determine whether or not they should be added to the list of indispensable food elements. There is still a great deal to be learned about the functions of all the inorganic elements essential to good nutrition.

Fortunately many of the essential inorganic elements are so widely distributed in plant and animal foods that there is little danger of a real shortage of them in the varied diet of human beings. The experimental feeding of animals has been the tool by which the indispensabil-

ity of many inorganic elements was discovered. Our present knowledge of the vitamins presents a similar situation. For these reasons nutritionists are agreed that man should provide himself with a wide variety of foods. In so doing the nutritionist endeavors to make certain that nothing indispensable to good nutrition shall be lacking. This is the only means at hand to safeguard the present lack of knowledge of how to compound a thoroughly adequate diet from chemically known substances. This appeal for variety in food selection is an appeal to sound common sense in view of the limitations of our knowledge of nutrition. There is no jest in this advice. The monotonous undiversified diets the world over are those most frequently associated with nutritional deficiency diseases. The medical profession should be on its guard against the long continued use of such diets in the treatment of special diseases.

Of the recognized nutritionally essential inorganic elements, calcium, phosphorus, iron and iodine need special attention because optimal amounts of these are least likely to be provided by hit and miss methods of food selection. The body adapts itself to a rather amazing extent to low intakes of these elements and conserves in large measure the allowances provided. But many times this is a forced and compromising adaptation that only softens or postpones the period of nutritive failure. Inadequate calcification of the skeleton of adults is a good example of this. The pliable bones of young children and the well calcified skeletons of adults can withstand amazing impacts of force without giving way to breaks or fractures. But almost every physician knows many adults who suffer these troubles as a result of insignificant little jolts or tumbles, particularly adults of middle age or beyond. Perhaps some of this is due to decreased secretion of certain hormones, but it is quite likely that much of it is due to their settling on a diet too largely of toast, tea and a little cake. If the body is forced to lose a little of its calcium and phosphorus day after day the time must come when the rarefaction of the bone makes it a very weak structure. It is a relatively simple matter to keep the skeleton well calcified once it is so, but of the possibility of recalcifying an adult skeleton that has lost a lot of its calcium and phosphorus I am not so certain. It is quite clear that further light is needed on this matter. For the present, the best advice that can be offered is to supply the body with liberal amounts of calcium and phosphorus as the bone develops the new structures in which these elements can be deposited and to keep right on supplying about 0.7 Gm. of calcium and about 1.3 Gm. of phosphorus daily thereafter. If the skeleton is already rarefied in inorganic elements, these quantities of calcium and phosphorus will at least prevent further rarefaction as far as proper food can protect this. A weak skeleton is a hazard in the ordinary pursuits of living as well as in the industrial occupations.

Among the common food items, not one is superior to milk as a source of calcium and phosphorus. A pint of whole or skim milk a day for every adult or the equivalent of this in the form of evaporated or dried milk would be of tremendous help in sustaining a good nutritive state in adults. And there is no need to parry the question of how to use it, for that is hardly worth the candle—consume it as you will. The popular excuse of many adults for evading the use of milk is that it makes one fat. A pint of milk carries approximately

300 calories and no flight of the imagination is going to make it any greater. A pint of milk is no match for calories as compared with most customary desserts. There would be no better way to improve the nutritive state of industrial workers than to see to it that each one gets at least a pint of clean pasteurized milk a day.

An iron intake of from 10 to 15 mg. a day for a man or woman has been widely used as a guide to planning adequate diets. Further knowledge about the variations in the availability of the iron in different foods has added some new problems to the evaluations of iron requirements. In the average American diet the principal sources of iron are eggs, leafy green vegetables, lean meats, mature beans and peas, and whole grain cereals.

able iodine also provide appreciable amounts of the iodine needed by man. The regions in which iodine deficiency is common are now generally known, and this condition can be treated prophylactically by the use of iodized salt or administration of potassium iodide under adequate medical supervision. Orr and Leitch,⁹ having reviewed the meager data at their disposal on actual iodine requirements, estimate therefrom that adults probably need around 0.045 mg. of iodine daily. The thyroid gland has the capacity to store iodine administered in excess of daily requirements, so that if it is necessary to administer iodides this need not be done often.

The one requirement for inorganic elements of special concern to certain groups of industrial workers is that

* From the 1939 Yearbook of Agriculture (Food and Life).

The body naturally has nothing to gain by the ingestion of unavailable forms of iron, so that analysis of the total iron in foods is of small help unless it is also known what proportion of such iron is available. The allowance of from 10 to 15 mg. of iron for adults was based on studies of iron balances; the iron absorbed from the food could have been none other than available iron. As a result of more recent studies this allowance appears to be generous. In consideration of what data there are about the availability of iron in different foods, it would appear that the provision of from 10 to 15 mg. of total iron in the form of a mixed diet of natural foods would probably meet the more recently established estimates of an adult's iron requirements.

Ingestion of generous amounts of sea food is one way to provide for an adequate intake of iodine. The iodine in sea food is absorbed by marine organisms from the sea water, which contains about 25 parts per million of iodine. In the case of certain marine fishes, ingestion of seaweed, a very rich source of iodine, accounts for further accumulations of iodine in such fish. Drinking water and vegetation grown on soil containing avail-

able sodium chloride. The average adult ingests from 10 to 20 Gm. of sodium chloride daily, the major portion of which is added as seasoning for foods. Hard work accompanied by profuse sweating or exposure to excessively high temperatures and low humidities, such as in furnace rooms, may readily lead to serious salt depletion accompanied by "heat cramps." The individual variation in salt concentration of sweat is very large. A man working under conditions involving profuse sweating may lose 8 or 9 liters of sweat in one day. If the sweat is of high salinity, the loss of salt could be on the order of 30 Gm. During acclimation of men to high temperatures, the salt concentration of the sweat is high the first few days and may decrease by more than 50 per cent during adaptation to such an environment. It is important, therefore, that new men engaged to work in an excessively hot environment be given plenty of extra salt from the start. A 0.1 per cent solution of sodium chloride in water at about 46 F. was found to

9. Orr, J. B., and Leitch, I.: Iodine in Nutrition: A Review of Existing Information, Special Report Series No. 123, Medical Research Council, London, His Majesty's Stationery Office, 1929.

be very acceptable to men working in a high temperature environment at the Youngstown steel mills and was very successful as a prophylactic for heat cramps. The volume of sweat lost as a result of continued occupation at a job involving work in high temperature environments is changed but little as time goes on. This loss of water needs to be replaced, and Talbott and

protective foods. Such diets will provide all the known essential food nutrients in adequate amounts and in addition furnish some measure of safety against inadequacies of essentials about which there is at present no knowledge. It is absolutely certain that all the essential food factors have not yet been discovered.

Although there are many published estimates of the human requirements for several of the well known vitamins, the scientific basis for these estimates leaves much to be desired. This situation is inevitable when one stops to consider that the criteria for recognizing borderline states of vitamin deficiencies are entirely lacking in the case of some of the well known vitamins. Probably no one is entirely satisfied that such criteria as have been employed are adequate for the purpose. Under these circumstances the best that can be done is to suggest tentative allowances that embody liberal margins of safety. Such daily allowances for an adult would be something on this order:

Vitamin A, from 5,000 to 6,000 international units.
Thiamin, from 1 to 2 mg.
Ascorbic acid, from 60 to 70 mg.
Vitamin D, unknown.
Riboflavin, from 1 to 2 mg.

The estimate for vitamin A provides some margin of safety over the amount required to restore normal dark adaptation in adults exhibiting mild degrees of night blindness. The estimate for thiamin provides around a 100 per cent increase over that of diets which barely prevent mild degrees of beriberi. The estimate for ascorbic acid is probably at least twice the amount that will prevent recognizable signs of scurvy. In the case of thiamin and ascorbic acid one ought probably to aim at the upper limits of these allowances so that cooking losses for these heat-labile vitamins do not reduce the actual intake below the lower limit. Vitamin D is undoubtedly necessary for adults, probably in considerably lesser amount than children require, but there is no basis for a quantitative estimate. The riboflavin

Coombs¹⁰ recommend that salt be given, at least to the extent of 15 Gm. a day, in addition to that contained in the diet, but that no attempt be made to limit water intake.

VITAMIN REQUIREMENTS

Altogether too much dramatic effort has been released on the subject of vitamin deficiency diseases and on the benefits purported to accrue from ingestion of large amounts of vitamin preparations. The general public has generously responded with purchase of vitamin concentrates to the extent of a money outlay of not less than \$100,000,000 during the past year. There are cases of vitamin deficiency diseases in the United States, but by far the larger proportion of these unfortunate persons are among those who have not and could not afford to buy vitamin concentrates.

For the treatment of vitamin deficiency diseases, the use of vitamin concentrates is amply justified. Some of these diseases are associated with diminished capacity to absorb vitamins normally when administered orally. In such cases appropriate routes of injection are clearly indicated.

From our present knowledge of the composition of foods, it seems almost impossible that a person could contract a vitamin deficiency disease without having subsisted for a considerable time on a diet inadequate in several respects at one and the same time. The inadequacies are not even limited to the recognized vitamins. An analysis of the diets of pellagrins, for example, reveals that their diets have been wretchedly inadequate in many respects. The only sound and permanent solution to the problem of malnutrition is to educate the people and adjust the economic situation so that everybody can share the benefits of a steady, well balanced diet. To do this occasions the need for a much larger consumption of the so-called protective foods—eggs, dairy products, tomatoes, citrus fruits and leafy green vegetables. There is no known substitute for a steady, well balanced diet carrying liberal quantities of the pro-

estimate is pretty much a surmise, based on quantities that accompany diets adequate in other known food essentials.

For the remainder of the recognized vitamins there are no general estimates for requirements.

A PRACTICAL GUIDE TO PLANNING ADEQUATE NUTRITION FOR THE INDUSTRIAL WORKER

It is all very well to discuss the nutritive needs of the industrial worker in terms of energy, protein, inorganic elements and vitamins, but embodying all this knowledge into a simple practical plan is quite another

10. Talbott, J. H., and Coombs, F. S.: Certain Aspects of Mineral Requirements. J. Am. Dietet. A. 15: 631-638 (Oct.) 1939.

matter. At this point it must be remembered that the industrial worker is usually a member of a family group who eat together at the same table. In addition, any practical diet plan must take into account the fact that families have some preferences in the choice of foods; the plan must be adjusted to fit the pocketbook, and the food should be attractive and pleasing.

The foods common in this country can be classified into about a dozen major groups. Suitable quantities of foods in these several groups can be combined to provide adequate nutrition over a period of a year, a month or a week for individuals of different age, sex and activity. Of course many combinations of these twelve major food groups can be worked out so that all the nutritive requirements which have been discussed in this paper will be amply provided. As an example of such a combination, table 1 shows the respective quantities of food in each group that will provide these nutritive essentials over a period of one year, listed opposite the descriptions of each type of family member. This particular combination of major food groups is one that can be provided at a relatively low cost. When the family composition is known it is a simple matter to read off in each of the twelve columns the quantities of foods that will supply the nutritive needs of individual members of the household. Simple addition of these quantities will provide the totals required by the family during the period of one year. If each of the sums is divided by 12 the results will give the quantities of foods in each major food group required by the family for one month; if divided by 50, the result is the approximate weekly quantities needed by the family.

If a family consisted of one moderately active man, one moderately active woman, a 5 year old daughter and an 8 year old son, this family's food requirements could be adequately met by weekly supplies of the kinds and quantities of foods (shown separately for each member of the family) indicated in table 2. These weekly allowances of food provide for the approximate daily intake of calories, protein, fat and carbohydrate as well as certain minerals and vitamins in the quantities shown in table 3.

The weekly cost of this food for these four persons would vary somewhat depending on current prices of food in the particular locality in which the family lived. According to prices reported in 1935-1936 by families of wage earners and clerical workers living in a wide range of localities in the United States, with adjustments made in accordance with trends in price levels obtained from the Bureau of Labor Statistics, this family's total food bill for one week during the period January to October 1938 would have varied (depending on the locality) between \$6 and \$9.50.

This diet plan provides for choice in eight of the twelve food groups as to which particular foods in the group the family elects to eat. For reasons discussed earlier, the family is urged to introduce as much variety as possible in its choices within those food groups which provide for choice. According to surveys based on about 4,000 records of weekly food consumption, Stiebeling and Phipard⁸ report that approximately 50 per cent of employed wage earners and clerical workers in various cities of the United States actually spent enough money for food to obtain diets of this nutritive quality. Although they actually spent enough money to get a diet as good as the one suggested in table 1, the actual food selection of many of these families was such that the nutritive value fell short of this plan. The remain-

ing 50 per cent did not spend enough money to obtain a diet with as good nutritive value as that suggested for a good low-cost diet in table 1. The practical problem of good nutrition is often, as was shown in these studies, a combination of educational and economic factors.

The plan of food selection outlined in table 1 is offered merely as a sample plan to show how the industrial workers and their families might solve the problem of adequate nutrition without undue expense.

PRESENT STATUS OF BENZENE

P. A. DAVIS, M.D.

AKRON, OHIO

In order to dispel any confusion concerning the present status of benzene, it is necessary to have a very definite differentiation between benzene and benzine.

Benzene (benzol C_6H_6)¹ is a single chemical substance obtained by distillation of coal tar and is purified by redistillation at from 70 to 80 C. Gasoline, or benzine,² is obtained from the distillation of petroleum and is a mechanical mixture of hydrocarbons ranging from C_5H_{12} to C_6H_{14} . Its composition varies according to the boiling point. At 36.3 C. it contains from 60 to 70 per cent of pentane, C_5H_{12} . Substances distilling between 30 and 70 C. produce what is commonly called gasoline.

Benzene is obtainable in several grades in commerce:

1. Benzene: Chemically pure (U. S. P. XI, p. 85) 95 cc. distils between 79.5 and 81 C.

2. Benzene 90 per cent: This is 90 per cent of the distillate up to 100 C. Composition from 80 to 85 per cent benzene, from 13 to 15 per cent of toluene, 2 or 3 per cent of xylene and 1 per cent heavy residue.

3. Benzene 50 per cent: This is 50 per cent of the distillate below 100 C., 90 per cent below 120 C. Composition from 45 to 50 per cent benzene, heavy residue of olefins, paraffins and complex bodies and some toluene.

4. Solvent naphtha: Consists chiefly of xylene, a small amount of toluene and thiophene.

A thorough knowledge of the difference between benzene and gasoline will, I believe, explain the diminishing number of cases of poisoning by the volatile hydrocarbons of the benzylic series. Benzene, toluene, xylene, naphthalene, anthracene and phenanthracene belong to the benzylic series and contain one or more carbon rings. Gasoline, on the other hand, does not belong to this series but to a lower unsaturated carbon-hydrogen combination commonly called the marsh gas series.

Pure benzene is a chemical entity, while all gasolines vary over wide ranges in composition. Commercial benzene has the following impurities in varying amounts: xylene, toluene, phenol, thiophene, carbon bisulfide, acetonitrile, pyridine and traces of many other substances.

Gasolines have no definite composition; for example, gasoline from Pennsylvania contains pentane, hexane, heptane and paraffins while gasoline from California and Texas contains cyclopentanes, cyclohexanes and cycloparaffins.

Read before the Section on Preventive and Industrial Medicine and Public Health, at the Ninetieth Annual Session of the American Medical Association, St. Louis, May 19, 1939.

1. Benzene (C_6H_6 or PhH = 78.08; benzol [German], benzole [French] phenylhydride, cyclohexatrienne, phene) is a colorless liquid or crystals with a density at 20 C. of 0.879, melting point 5.4 C., boiling point 80.3 C.; insoluble in water and miscible with alcohol and ether, acetone and glacial acetic acid.

2. Benzine, or gasoline, is a mixture of hydrocarbons obtained from the second portion of the fractional distillation of crude petroleum which consists of the fraction boiling between 70 and 90 C. A clear colorless liquid with a density of from 0.640 to 0.675.

USES

Benzene has the following uses:

1. As a solvent for paints, lacquers and varnish, rubber and fats.
2. In color printing.
3. As a cleaning agent for clothes.
4. As a motor fuel.
5. In the chemical manufacturing industry.

Both benzene and gasoline are poisonous but benzene is quicker in its action, and the intensity is much greater. There are three avenues of entrance of benzene into the body: (1) the respiratory system, (2) the alimentary system and (3) the skin.

It is my opinion that in from 90 to 95 per cent of cases the benzene enters by way of the respiratory system, the incidence of cutaneous absorption being very small except in those cases in which the hands and arms are immersed in solutions containing a large percentage of benzene or when the hands are washed in benzene to remove grease and rubber. This procedure, however, should be condemned.

Absorption by way of the alimentary system is not great but often occurs when materials are introduced into the mouth or food that has been in the same room with the benzene is eaten or tobacco that has been exposed to benzene fumes is put into the mouth. A small percentage of benzene is dissolved in the mucous secretions of the mouth and throat and swallowed. The greater the concentration of the fumes, the greater the amount absorbed by the skin and the alimentary tract, but under controlled conditions these two avenues of absorption are practically negligible.

The human system can tolerate minute amounts over a period of many months if proper aeration and elimination are instituted. In other words, a small factor of immunity develops through an equilibrium between intake and output of absorbed material. Just as soon as a minute increase of intake over output develops, symptoms begin to appear.

The following clinical symptoms seem to me to be the most predominating after observing and examining between 6,000 and 7,000 men and women who have worked with the various compounds containing benzene or its homologues for the last twenty years:

1. Peculiar brackish taste.
2. Slight giddiness.
3. Unsteady vision and slight headache.
4. Nausea and vomiting.
5. Dizziness, "benzene jag," odor of benzene.
6. Weakness. Benzene breaks down the body defense against acute infections and many secondary conditions develop, such as (a) gingivitis, (b) boils, (c) pustular conditions of the skin, (d) frequent colds, (e) arthritis and (f) infections of the gastrointestinal tract. Hektoen has done much work on the effect of benzene on antibody formation.
7. Increased nervousness with increased pulse, nosebleed, uterine bleeding, bleeding from the gums.
8. Slight temporary increase in blood pressure.
9. Excessive fatigue at the end of eight hours' work.
10. Marked tremors of the hands.
11. Loss of equilibration in the dark.
12. Gastric and intestinal disturbances.
13. Paresthesia—numbness, tingling.
14. Insomnia—in the first stages drowsiness and in later stages insomnia.
15. Loss of weight, benzene pallor.
16. Benzene purpura, nosebleed, anemia.

17. Menstruation every two or three weeks by female employees.

18. Dermatitis.

19. Nephritis.

20. Labored respirations and coma.

With reference to anemia under paragraph 16, it may be said that many thousands of blood counts have shown that this is one of the main factors that the industrial physicians must rely on to show the effect of benzene on the individual. There first develops a slight leukocytosis, later a slight leukopenia, and erythropenia with a slight reduction in hemoglobin content. With increased absorption this progressively gets worse, and the following develops:

1. Increased leukopenia.
2. Increased erythropenia.
3. Lymphocytosis.
4. Development of few transitionals. A point is reached when the blood forming organs are nearly suppressed and the new cells do not form rapidly.
5. Decrease in coagulation, caused by a decrease in prothrombin and thrombin.
6. Decrease in blood calcium.
7. Decrease in antibody formation.
8. Severe decrease in hemoglobin formation with increase of hematin in the urine and decrease in blood platelet formations.
9. The beginning of endothelial lining cells to appear in the blood stream. The appearance of these cells indicates the serious if not the fatal stage of poisoning.
10. Complete cessation of formation of new blood cells.

I have observed in a few cases a condition of vacuolation in the leukocytes, but this is not a constant factor. It probably is due to the inability of the cells to retain fatty compounds, and I believe that fatty substances are either extracted or prevented from forming in the nerve tissue, thus producing the nervous complex. The effects of benzene are accumulative, more lasting and more severe than those of gasoline.

Temporary exposure to slight concentrations of benzene or gasoline are transient, and complete aeration causes the effects to disappear. It is the constant absorption of small amounts daily that produces the detrimental effects.

In October 1935 Yant and Sayers and their associates⁴ presented a new method for controlling exposures to benzene by the determination of urine sulfates. Since Dr. Yant and his associates advocated this method of detection of the absorption of benzene, I have inaugurated it as a routine procedure for all patients who work with benzene. During the last ten months I have studied 650 workers with the inorganic sulfate method in conjunction with blood work, physical examinations, analysis of the air and any other clinical examinations which I thought might throw some light on this method. From my experience I have found several factors, which I shall mention:

1. In most industries using large quantities of benzene the fire hazard is great; when it is possible, some other solvent is combined with benzene to reduce the flash point of the benzene. The nature of the solvent determines the accuracy of the test. For example, carbon tetrachloride is often used; it causes the opposite effect from benzene on the sulfates and therefore, unless there is an extreme reduction, the results are not useful as a diagnostic factor. Ethylene dichloride is another solvent that is used with benzene and changes the results.

4. Yant, W. P.; Schrenk, H. H.; Sayers, R. R.; Horvath, A. A., and Remhart, W. H.: *J. Indust. Hyg. & Toxicol.* 18: 69 (Jan.) 1936.

2. There is some variation on different days in the same individual working under the same concentrations. I have found that in some cases the inorganic sulfates in the urine are as low as 50 per cent one day and a recheck the following day at the same time and with the same concentration shows them to be 80 per cent. If this were a single case I would say that the discrepancy was due to technic, but a careful check of all reagents was made and controls were run to eliminate the possibility of error. I have made it a regular rule to have all urines below 70 per cent rechecked, and if this concentration persists I know that there is something wrong in the ventilation or that the individual is absorbing benzene from some other source.

3. Atmospheres containing from 100 to 115 parts per million in eight hours have but little effect on the inorganic sulfates, but over a period of time there is a slight change of from 8 to 10 points. I have not noticed any change in the blood when the concentration has ranged between 100 to 125 parts per million.

4. Alcohol and certain foods cause a change in the daily sulfates.

5. It has not been determined how long a person can work with inorganic sulfates below 50 per cent before a change in the blood occurs. I have several workers who have been working for one year and four months, with their inorganic sulfates fluctuating from 56 to 82 per cent, and their blood and all other examinations normal. These men are examined completely every month, and at the slightest change in the blood picture they are removed from contact with benzene. On several occasions I have found the inorganic sulfates between 8 and 10 per cent when the person had been cleaning clothes with benzene, but in two days, after there was no contact with benzene, the inorganic sulfates were up to 75 per cent.

However, may I impress the point of rechecking all cases in which the ratio is less than 70 per cent: if the percentage is 50 per cent or less two courses must be taken: The person must be removed from contact with benzene and the ventilation must be corrected until air samples show from 100 to 115 parts per million.

The accompanying table shows one of the numerous surveys made and the correlation between the concentration of benzene, inorganic sulfates and the blood picture.

This experiment shows the value of making frequent urinary sulfate determinations for the control of benzene absorption.

PREVENTIVE AND CORRECTIVE MEASURES

1. *Ventilation and Safety Devices.*—This is one of the most important factors. To keep the concentration of benzene in the atmosphere below a certain point one must recognize the fact that benzene fumes are heavier than air and that they are very diffusible. Ventilation from the floor by means of suction is preferable to overhead ventilation. Ventilation must be general, for benzene fumes form pockets. Benzene fumes liberated on one floor may produce a rather high concentration on a floor below if suction ventilation is not used.

2. *Healthy Persons in Operations Using Benzene.*—My experience has shown that undernourished, anemic persons or those afflicted with bronchitis, any pulmonary condition or cardiac or kidney infections should not be placed where they come in contact with benzene or gasoline fumes. Female help, as far as possible, should

not be placed where there is a very high concentration of any of these fumes, for no matter how healthy they are they begin to have menstrual disturbances after some absorption.

A certain group of persons can tolerate a large amount of benzene and show but little physical effect. Those who are shallow breathers seem to be less affected than the deep breathers. There appears to be some relation between the permeability of tissue diffusion in the lung tissues and the amount of absorption which causes physical symptoms to appear. Persons addicted to alcohol seem to tolerate benzene or gasoline fumes to a greater extent than others. I attempt to place only those in fine physical condition on operations in which benzene or any allied product may have to be used, and I believe that it has been worth while.

3. *Education Program.*—Proper instructions to the supervisors and the workers in all departments in which any volatile substances are used, such as benzene, gasoline, carbon tetrachloride or other such substances, are

*Correlation Between Concentration of Benzene, Inorganic Sulfates and Blood Picture**

very important. They should be told of the properties of the substance they are using, what conditions might develop from excessive inhalation or exposure to it and how these conditions can be successfully prevented by taking precautions and obeying the instructions given.

4. *Frequent Examinations.*—All persons should be examined before being allowed to work in these departments. They should have examinations every thirty to ninety days, according to the concentrations of the vapor in the various departments. If examination of the blood, urine, blood pressure, vision, sensation and equilibration shows any indications of absorption, the person should be transferred to some other job. Workers are advised of general health principles and methods of elimination of absorbed benzene.

5. *Substitution Products in Place of Benzene.*—Many substitutions have been tried to replace benzene, such as its higher homologues toluene, naphthalene and xylene and other solvents of the unsaturated hydrocarbons. My experience has been that gasoline is less poisonous and will eventually replace benzene in nearly all operations until a better nonpoisonous solvent is found.

Batchelor⁵ has done some remarkable experimenting with benzene and some of its higher homologues by using intraperitoneal and subcutaneous injections and inhalations in groups of animals. His conclusions are that toluene, xylene and hi-flash naphtha are vastly superior from a toxic standpoint and are practically devoid of the industrial hazard involved in the use of benzene. This statement is true with regard to the relations of the toxicity, but I do not believe that toluene, xylene and hi-flash naphtha can be so lightly considered.

It is not occasional exposure to these compounds that causes the harm but the daily exposure over long periods of time. Various mixtures, under commercial names, have been tried for solvents in order to reduce the flash point, thereby reducing the fire hazard. These invariably contain carbon tetrachloride. Carbon tetrachloride in small quantities, when inhaled, causes extreme nausea and often severe vomiting and should be used only in closed systems of ventilation. I have found that gasoline works almost as well as benzene in most operations, and the number of cases of dizziness and nausea has been reduced to a minimum.

Hemoglobin and red cell count not affected; insufficient exposure; exposure controlled by urinary sulfate determinations.

Many things must be considered before the use of a substitute product in industry is advocated:

1. Is it injurious to the human being?
2. Is its operation more or less efficient?
3. Is its operation more or less expensive?
4. Does it require a large outlay of expense to install?
5. What is the competitor using and what is the quality of his product?

It requires very close cooperation between the medical department, the chemical department, the safety department and the production efficiency department to arrive at a proper conclusion.

METHODS OF CORRECTING CONDITIONS

The methods of correcting conditions when volatile substances are used resolve themselves into a very definite procedure:

1. Experimentation and research made on the substance used as to its detrimental effects on the human system. If such a substance causes detrimental effects, three main recommendations should be made;

A. Discontinuance of the substance, and if this is not possible, then

B. Substitution of an allied substance not so detrimental, and if this is impossible then

5. Batchelor, J. J.: *The Relative Toxicity of Benzol*, Am. J. Hyg. 7: 276 (May) 1927.

C. Use of the substance in a closed, airtight system, which prevents dissemination of the gases, or institution of suction ventilation, depending on the nature of the substances as to whether its gaseous form is heavier or lighter than air.

2. The rotating of the individuals who work with the substance to other jobs.

3. Use of gas marks. This has not proved very practical in industry.

4. Frequent examinations: Removal from the job of any one showing signs of poisoning, such as: (1) persistent urinary sulfates below 70 per cent; (2) slight purpura or hemorrhage from mucous membranes or other organs; (3) reduction in white cells of 1,500 below normal (a 7,000 count is assumed as normal); (4) reduction of red cells of from 10 to 15 per cent below normal; (5) reduction of hemoglobin below 80 per cent, and (6) slight variation in coagulation time.

TREATMENT

A person who, on examination, shows any effects of a solvent such as benzene or its homologues, gasoline or its derivatives or carbon tetrachloride, is immediately removed from contact with the substance. The treatment proper of benzene consists of: (1) elimination; (2) aeration, oxygen inhalations; (3) treatment of gastric disturbances; (4) treatment of secondary anemia; (5) supportive measures for the heart and protection of the kidneys; (6) stimulation of the blood-forming organs by use of iron compounds, reticulogen, liver and spleen substances, transfusions and roentgen therapy to the long bones; (7) nourishing food with an excess of animal fats; (8) increase of the calcium intake, and (9) intravenous saline and dextrose.

CONCLUSION

Experience has shown that benzene and its derivatives present a very definite and serious industrial health hazard. The primary effects of these substances are produced on the blood and blood-forming organs with secondary involvement of the nervous system and other organs. In high concentrations they cause acute poisoning, often with sudden death, and in low concentrations a slow but chronic poisoning. The hazard can be perfectly controlled by certain definite procedures:

1. Proper ventilation.
2. Substitution of less poisonous solvents.
3. Frequent examination, and the early removal of any one showing slight symptoms of poisoning, as detected by a low urinary sulfate determination.
4. Proper education of the supervisors and workers.
5. Close cooperation between the production and medical departments.
6. Establishment of physical standards for those who are going to work with benzene or any of its homologous compounds.

633 East Market Street.

ABSTRACT OF DISCUSSION

DR. A. G. CRANCH, New York: The warning is still timely not to confuse benzene with benzine. The two products are different technically and in toxicity. There are also various impurities in commercial benzene. With regard to early case finding, much emphasis is often placed on blood counts showing reduction in leukocytes and red cells. Dr. Davis has warned of the leukocytosis which sometimes precedes the leukopenia and may be misleading. Urinary tests furnish a practical guide, but Dr. Davis well emphasized the pitfalls: the

errors due to mixed solvents, the daily variations which may occur in the individual case and the failure at times to obtain a significant test even in the presence of dangerous exposure. In preventive work it is well to remember the heaviness of the fumes. This condition is present with many industrial solvents and calls generally for lateral or down draft for its removal. I would stress the value of education. I have had good results by particularly instructing workers not to inhale the fumes recklessly, and in case of an unusual or temporarily increased exposure they almost involuntarily withdraw and cease to breathe deeply. There are dangers in substituting other solvents for benzene, as sometimes the substitute may prove to be equally or more toxic. This is true also in some cases in which benzene has been diluted with other solvents. I would ask Dr. Davis what he can tell us as to recurrence of serious symptoms among patients who had apparently returned to normal after treatment for benzene poisoning. Such apparently cured persons with a normal blood picture after a slight intercurrent infection like influenza sometimes seem rapidly to grow worse. Is this usually the case? Something to bear in mind with regard to benzene poisoning is that in the patients' subsequent life great care should be exercised to avoid the exposures which might reactivate their symptoms.

DR. LOUIS SCHWARTZ, New York: As Dr. Davis stated, the use of benzene in industry is diminishing and its place is being taken by solvent naphtha or some other agent which is less toxic. Toxic symptoms usually occur from inhalation of these substances and not from contact with the skin. Dr. Davis has said that 95 per cent of the cases of benzene poisoning are due to inhalation. That is true because when these substances are inhaled they are inhaled in minute proportions and taken into the body; they do not irritate the mucous membranes or the skin. If the skin is exposed to them in concentrated form, it is defatted and blistered and its absorptive qualities are impaired. This is true of all the volatile solvents; those substances do not inflame the skin but penetrate it, and they are more likely to cause toxic reactions than those which inflame the skin. Most of these volatile solvents take the fat out of the skin. Persons who have greasy skins can withstand their action much better than those who have dry skins. This brings up the point of how to prevent dermatitis from these substances. When a person handles them he should rub olive oil or some other animal or vegetable fat into the skin to replace whatever fat has been taken out by the solvent. Another way of preventing dermatitis from these substances is to wear gloves; rubber gloves ordinarily do not withstand the action of these solvents and are easily soluble in them, so synthetic rubber should be used because that stands up much better. I should like to ask Dr. Davis what his experience has been in noting symptoms of dermatitis in cases of benzene poisoning. He will probably tell you that dermatitis is not common among those who suffer with benzene poisoning, and those who suffer from dermatitis are not so likely to have benzene poisoning.

DR. P. A. DAVIS, Akron, Ohio: In answer to Dr. Cranch's question in regard to the recurrence of symptoms with some concurrent infection, I do not believe that the patient has been discharged as completely cured before he has this condition. For instance, I had occasion recently during an epidemic of influenza to observe several men who, while they had a low urinary sulfate level, around 60 or 70 per cent, were taken off the job and subsequently contracted an influenza infection. They returned to normal slowly, probably because benzene absorption had produced some effect on the myelogenous tissues and on the spleen and prevented the normal return of the blood cells. I recall a case in which a man had had acute benzene poisoning and there developed definite leukopenia and erythropenia; his urinary sulfates returned to normal in three weeks and his blood to 95 per cent. The red and white cells returned to normal. He was not put back in contact with benzene but was placed in another position entirely free from any volatile substances, and influenza developed. After his influenza apparently cleared up he still seemed to have benzene

poisoning, and the only explanation I have for that is that the blood-forming organs had not returned to normal before he had a subsequent infection or some other involvement. It takes a long time for the blood-generating organs to return to normal antibody formation. They remain as a stationary factor for some time after the blood picture and the urinary sulfate picture have assumed a normal status. With regard to the dermatitis caused by benzene, acute benzene poisoning does not necessarily show up as a skin condition at all. The dermatitis from benzene is contact dermatitis and not systemic dermatitis. In only a few cases does systemic dermatitis result from benzene poisoning. With regard to protection of the workers, I have a hard time convincing the engineers that, since nobody has been killed or poisoned while manufacturing these materials, no one should be poisoned or killed while using them. If proper protection is given, whether against benzene, a halogenated compound or any other volatile substance with toxic effects, by masks or whatever safety devices are available, I do not think any trouble will be experienced. The organization with which I am connected has instituted the use of a wax ointment. Men who are going to work with benzene smear it all over their hands, arms and faces. This ointment is not soluble in benzene, so they have little absorption but sufficient skin protection. I think there must be external protection against all these substances if acute absorption is to be avoided.

THE CARDIOPATHOLOGY OF HEATSTROKE

GALE WILSON, M.D.

SEATTLE

Under the term "heatstroke" are herein included four deaths from hyperpyrexia, one caused by insolation or "sunstroke," and three from artificially induced pyrexia by the so-called fever machine.

Historically this affliction is as old as Biblical times, being described in 2 Kings (Osler¹). The early Arabians felt that Sirius, the Dog Star, in some way was responsible for the symptomatology and called the disease "siriasis." During the British occupation of India and subsequently, heatstroke has received considerable attention, but the pathologic condition in the fatal cases has apparently been decidedly secondary to the clinical manifestations. Osler¹ dispenses with the morbid anatomy in these few words: "Rigor mortis occurs early and putrefactive changes may come on with great rapidity. The venous engorgement is extreme, particularly in the cerebrum. The left ventricle is contracted (Wood) and the right chamber dilated. The blood is usually fluid; the lungs are intensely congested. Parenchymatous changes occur in the liver and kidneys."

Webster² also dismisses death from heatstroke with this concluding sentence: "The autopsy findings will be those due to either syncope or asphyxia." From the condition at autopsy of the four cases to be presented it would appear that the cardiac lesions found in all the cases closely approximate those found in death from electricity or lightning as described by Kratter (quoted by Webster) and consisting of "subendocardial ecchymotic extravasations combined with bloody emphysema of the larger bronchi." Wood³ adds nothing to Osler's description of the morbid anatomy.

REPORT OF CASES

CASE 1.—C. O., a white man aged 45, a laborer, had been out of work for several months. September 15 he reported for work with a logging crew, working as a sawyer. By a coincidence this day was one of the hottest days of the year, averaging about 92 F. in the woods where the crew was working. At noon the man came to the mess shack but did not feel very well, said he was "sick to his stomach" and drank only a cup of coffee. Returning to work after the lunch rest, he worked more slowly than his partner until midafternoon, when he suddenly dropped his saw, began to shout and tear his hair, and then ran off into the woods. Pursued by his fellow workers he was returned to the camp "raving mad and so hot he sizzled," according to the foreman. On admission at the hospital his temperature was 105 F. and he was unconscious. Two hours later (about four hours after the acute onset), and without regaining consciousness, he died with a temperature of 107 by axilla. At the autopsy, three hours after death, a purpuric spot deep in the right axilla, and a series of similar spots over the back and midportion of the left arm, were observed. The chest contained approximately 150 cc. of bloody fluid in each pleural cavity and there was marked pulmonary congestion with bloody froth in the bronchi. The heart showed a massive subendocardial hemorrhage on the septal and posterior walls of the left ventricle extending up under the base of the mitral valve. There were petechial spots in both kidneys.

CASE 2.—I. T., a white man aged 62, had "fever therapy" in a doctor's office. This was his second such treatment. It was started at 10 a. m., and at 1 p. m. the temperature was 106 F. and the heat was discontinued. At 2 o'clock he was removed from the machine and at 5 o'clock the temperature was still 106 and the patient was unconscious. At 8 o'clock he was admitted to the hospital in a deep coma and he died shortly after midnight without regaining consciousness, with a terminal temperature of 106 F. by axilla. The autopsy gave essentially negative results except for cerebral edema and congestion, and subendocardial hemorrhages throughout the septal and posterior walls of the left ventricle.

CASE 3.—F. J., a white man aged 23, always previously well, had "fever therapy" for a gonorrheal urethritis. He had been removed from the cabinet and his temperature was down to 101 F. by mouth when it suddenly began to rise and in spite of constant ice packs the heat rose to 110 degrees by axilla and he died approximately three hours after the temperature began to rise. Autopsy showed petechial hemorrhages on the right side of the chest and small extravasations of blood throughout the pectoral muscles. There was a massive subendocardial hemorrhage in the left ventricle involving the septum and the posterior wall, extending through the thickness to the septum. There were also petechial hemorrhages in the brain stem and kidney.

CASE 4.—M. L., a white man aged 26, was given "fever therapy" for the third time in a doctor's office. After removal from the machine his temperature had dropped to 101 F. by mouth when he had a convulsion and his temperature began to rise. He was sent to the hospital and packed in ice but his temperature continued to rise and at death, four hours after the convulsion, the axillary heat was 108.6 F. Autopsy revealed congestion of the brain with extravasations of blood about the superior surface of the cerebellum and a subendocardial hemorrhage in the left ventricle, rather generalized, but most marked in the septum in the region of the bundle of His.

COMMENT

In four deaths from hyperpyrexia, one "natural" and three "fever therapy" cases, the same type of heart lesion was present and yet all four persons before the fatal illness were supposedly in "good health." The predominant feature of the clinical picture is the tremendous rise in body temperature, accompanied by unconsciousness, and both probably caused by cerebral edema and later by actual petechial hemorrhages in the brain.

The most striking, and probably the actually fatal, mechanism is a rather extensive hemorrhage under the endocardium of the left ventricle, especially on the septal wall in the region of the bundle of His. In none of these cases were seen the gastrointestinal hemorrhages reported by Chunn and Kirkpatrick.⁴

509 American Bank Building.

DERMATITIS AMONG PLATE PRINTERS

P. A. NEAL, M.D.

Passed Assistant Surgeon, U. S. Public Health Service
WASHINGTON, D. C.

In a large printing establishment, a considerable percentage of plate printers had suffered for many years from recurrent cutaneous lesions of the hands and arms. So frequent were these lesions that the employees and the management requested an investigation not only because of the protests of the workers but also because of the financial loss due to compensation and time lost from work.

The establishment employs 1,058 workers, but most of the dermatitis occurred among the group of 318 plate printers and their forty-seven skilled helpers. This group of men lost thirteen man years of working time during the period of 1900-1936 at an estimated loss of \$50,000 in lost time, not counting compensation, cost of medical treatment and the sufferings of the workers.

Among the other 693 workers no records could be found of any lost time from occupational dermatitis occurring during this period.

OCCUPATIONAL PROCESS

The engraved plates are covered with ink by press rollers and the plate printer wipes the excess ink from the plates by passing the bare hands rapidly over the plate. The ink that accumulates on the hands is wiped off on an apron. The apron is usually heavily crusted with dried ink from continued use, showing that it is but infrequently changed. In the interval between wiping off the plates, the plate printer cleans the ink from used plates with a piece of cloth saturated with gasoline which he holds in his bare hands. In these operations the hazards to the skin are not only from simple contact with the ink and gasoline but also from having the ink rubbed into the skin.

To clean the hands, which is done twice a day, the plate printers use a common sink containing a light nonirritant mineral oil in which the ink is soluble. The hands are wiped off with cheesecloth which is kept in the oil. Following this, soap and water are used to remove the oil from the hands. Many of the workers, in addition to the soap and water, use a stiff brush for scrubbing and some use potassium carbonate with the brush, while others use white sand and still others use all these cleaning agents. The abrasive action of these mechanical cleaners and the keratin solvent action of the potassium carbonate were no small factors in the etiology of the dermatitis. As proof of this, twenty-four rotary press printers who have some ink exposure but whose work does not entail wiping the ink off the plates and who did not use the brushes for cleaning the

4. Chunn, G. D., and Kirkpatrick, C. L.: Fatal Result of Artificial Fever Therapy, *Mil. Surgeon* 81: 281 (Oct.) 1937.
Read before the Section on Preventive and Industrial Medicine and Public Health at the Ninetieth Annual Session of the American Medical Association, St. Louis, May 19, 1939.

hands had no dermatitis at any time. In fact, when plate printers complained of stubborn cases of dermatitis they were often transferred to the rotary press printing job, where the dermatitis disappeared. On the other hand, among the forty-seven skilled helpers whose job it was to clean the ink buckets and fountains with gasoline there occurred three cases of dermatitis. These workers were exposed to more gasoline than were the plate printers but were less exposed to the inks, and they also used the same cleaning methods as were used by the plate printers.

Actual examination was made of 389 workers. The occupational history was taken to determine the workers' entire industrial experience, which disclosed that the majority of the plate printers, rotary press printers and skilled helpers had spent their entire working time at these occupations at their present place of employment and that all the employees who had dermatitis of the hands incurred this condition while working at this establishment. The shortest length of time after

of the physical examination. Four types of cutaneous lesions were found: 1. Chronic inflammation of the skin characterized by erythema and papules which developed into vesicles varying in size from a millet seed to a marble. The vesicles were easily ruptured, leaving denuded areas and forming crusts. Scaliness and fissures often followed this crusting and remained for a considerable time. Occasionally infection of a ruptured vesicle resulted in the formation of pustules and ulcers. New crops of vesicles appeared from time to time and some of the patients stated that they had had this condition of the hands for more than fifteen years. The dorsum and the interdigital spaces, the palms and the wrists of both hands were usually affected. However, in a few cases the lesions were restricted to the right hand. Sixteen of the twenty-one plate printers had dermatitis of this type. 2. The three skilled helpers, whose work it was to clean the ink fountains and buckets, and two plate printers had chronic dermatitis of the hands and wrists characterized by induration,

Of the 318 plate printers, twenty-five had only an examination of the hands, and on eight no specimens for mycologic study were made.

employment that it took dermatitis to develop was eleven months and the longest about forty years. About one half the number of workers who had dermatitis had worked for ten years or more before they contracted it.

The past and present medical histories were taken in an attempt to tie up any allergic personal or family history with the susceptibility to the dermatitis, as well as in an effort to determine its origin and duration.

A history of familial allergy was about the same in all the groups examined, but it was found that a personal history of allergy was twice as frequent among those who had dermatitis as among those who had not. The season of the year played no role in the occurrence of the dermatitis. Thirty-eight per cent of the workers who were found to have dermatitis and 57 per cent of the workers who stated that they had had dermatitis lost no time from work because of their condition. The majority of the remaining affected employees lost from one week to two months' time from work as a result of their dermatitis.

The men were then stripped and examined for cutaneous lesions. Twenty-one plate printers and three skilled helpers had dermatitis of the hands at the time

roughness, dryness and wrinkling, accompanied by firmly adherent thin scales and no vesiculation. This type of lesion is characteristic of chronic dermatitis caused by long exposure of the skin to fat solvents. 3. One plate printer had a pustular perifolliculitis of the dorsum of the hands and plugging of the pores of the skin on the hands and forearms with numerous pit-like scars from healed areas of previous folliculitis. The dorsum of the hands and forearms of about 20 per cent of the plate printers showed enlarged pores plugged with dried ink. 4. Three plate printers had an eruption of the palms characterized by deep-seated vesicles, resembling dermatophytids. In addition, these men gave negative patch tests and had demonstrable fungous infections on other parts of the body.

Thirty-seven additional plate printers gave a history of having had dermatitis of the hands, which they considered due to their occupation. Three of these are now employed as rotary press printers and have had no dermatitis since that time.

In an effort to find what part fungous infections played in the etiology of the dermatitis occurring in this establishment, microscopic and culture examinations of material from the hands and feet of 354 of these

men were made. In this study a definite diagnosis of dermatophytosis was made only when pathogenic fungi could be demonstrated either by the microscope or by culture.

Pathogenic fungi were present in 129 cases (36.4 per cent). All the fungi were isolated from the feet—none from the hands. The lesions seen on the hands of the men did not resemble dermatophytoses. Moreover, there was no difference between the mycologic observations on the plate printers who had dermatitis on the hands and the mycologic observations on the other men examined who did not have dermatitis. Neither was there any difference in the frequency of occurrence of clinical evidence of dermatophytosis between these groups.

Patch tests were performed on 121 individuals, of whom eighteen were plate printers who had dermatitis of the hands at the time of examination. Thirty-three were plate printers who gave a history of dermatitis of the hands. As controls I used fifty plate printers who had been employed for ten years or longer and who had never had dermatitis of the hands, and twenty employees of the Industrial Hygiene Division of the National Institute of Health who never had known contact with any of the printing inks used. No positive reactions were obtained among the seventy controls given patch tests. Nine of the eighteen plate printers who had dermatitis at the time of examination gave positive reactions to the inks. Four of the thirty-three plate printers who gave a history of dermatitis of the hands gave positive reactions to the inks. Some of those who gave positive reactions reacted to more than one of the inks. Reactions were obtained only from orange, red, brown and yellow inks. The thirteen inks used in the patch tests were all of secret formulas and of complex composition, containing at least thirty coloring components in addition to various fillers, varnishes, oils and driers. I was informed that there are more than 1,000 different ingredients used in making these inks. Patch tests with the individual components of the inks could not be performed because their compositions are secret and therefore were not revealed to me.

Most of the dermatitis found in this establishment was undoubtedly of occupational origin, as is shown by the history and clinical appearance of the lesions and by the results of the patch tests. Dermatophytoses played but a small, if any, role in the etiology of these cases.

The actual causative agents were proved to be the inks and the cleaning materials used for the plates and for the skin.

The action of these irritants was augmented by mechanical trauma of the occupational process.

Hypersensitivity, acquired after exposure for a year or longer, was a factor in about 25 per cent of the cases, as was shown by the patch tests.

RECOMMENDATIONS

1. A complete preemployment examination should be made of plate printers by a physician who is aware of the hazards to the skin associated with these occupations.

2. Periodic medical examinations of plate printers should be made, particular attention being paid to the evidence of cutaneous diseases. Dermatitis of any employee should be carefully investigated and proper remedial measures instituted.

3. Workers handling cleaning fluids should, whenever possible, be required to wear rubber gloves with the sleeves buttoned down over the gloves in order to prevent the irritant chemicals from getting inside the gloves. Such rubber gloves should be made of synthetic rubber which is not easily affected by the volatile solvents.

4. Clean towels and clean aprons should be furnished to the workers daily.

5. The use of a common oil trough should be discontinued and some method should be instituted whereby each worker uses oil and cheesecloth not used by any one else.

6. The use of abrasive cleaning agents and strong alkalis should be prohibited. Only a good grade of liquid soap should be used.

7. Shower baths and wash rooms should be kept clean and scrubbed daily with soap and hot water.

8. Individual paper sandals should be furnished workers using the shower baths.

9. Separate lockers for work clothes and street clothes should be furnished plate printers to prevent soiling the street clothes with the inks and other substances capable of producing dermatitis.

National Institute of Health.

ABSTRACT OF DISCUSSION

DR. LOUIS SCHWARTZ, New York: Sometimes the reluctance of the managers of a company to reveal secret formulas may be overcome by asking them to put together groups of chemicals, not giving their names, for patch testing. For instance, all the dyes that went into the composition of the offending inks could have been mixed together without their names being divulged and the susceptible workers patch tested with the mixture to find out whether the dyes were the irritants. If a positive patch test resulted from this mixture of dyes, then the management could have been asked to divide the dyes into six groups of five dyes each, still not divulging the names of the dyes but only giving them numbers. Patch tests could then have been performed with the six groups of dyes and the group which gave the positive patch test would have been the one that contained the offending dye. The individual dyes in this group could then have been used for patch testing and the offending dye could have been identified by number and surely there could have been no objection from the management to give the name of the offending dye, provided the names of the ones that did not cause dermatitis were not mentioned. This would not have revealed a secret formula. The same procedure could have been followed with the various varnishes, oils, fillers and driers which went into the composition of the inks. It is inferred that removal to other jobs resulted in a cure of the dermatitis; but the paper also states that thirty-seven additional plate printers with a history of dermatitis no longer had it although they were still working at the job. This shows that these men had lost their hypersensitivity. I wish to emphasize that it is not advisable to remove employees with mild occupational dermatitis from their jobs before they are given a chance to get "hardened," as they call it. This losing of their hypersensitivity or developing an immunity actually happens in many cases if the man with dermatitis continues to work and gets well while on the job. In other words, continued exposure to a chemical sensitizes some workers, but most of those who thus become sensitized will become immune if they are allowed to continue to work. Of course, while working they should be given proper protective clothing as well as treatment for their condition. Only those should be taken off the job and transferred to other occupations who show that they cannot acquire this immunity. I would advocate that at least a month's trial at a job be allowed for those with mild involvement so as to give them a chance to become hardened.

A STUDY OF 2,400 ELECTROCARDIOGRAMS OF APPARENTLY HEALTHY MALES

HARRY J. JOHNSON, M.D.
NEW YORK

The chief hope of influencing favorably the mortality and morbidity of coronary heart disease rests with the earliest possible detection of its presence in an individual, as well as the elimination of predisposing factors. The only means available at present by which the presence of coronary disease can be detected before symptoms are present is by the electrocardiogram. Although one is not justified in attempting to diagnose heart disease from an electrocardiographic tracing alone, changes in the coronary circulation frequently occur which can be detected by electrocardiogram long before symptoms or signs become apparent. The extent to which disease must progress before symptoms become evident varies with individuals and is by no means constant. An exact relationship between the objective appearances in the electrocardiogram and the symptoms and progression of the disease has not been established.

A serial study of electrocardiograms in conjunction with the physical examination and an analysis of habits, occupation and diversions, beginning at a time when the coronary circulation is normal as judged by electrocardiographic appearances as well as subjective symptoms, and continuing at regular intervals through life, would be enlightening. By such means it might be possible to correlate habits, exercise, work and various physical factors with the onset and subsequent development of coronary heart disease. Such an investigation is now in progress.

This report is based on the study of 2,400 electrocardiograms taken as part of the periodic health examination of apparently healthy men. These were all policyholders with more than \$25,000 of life insurance in force, who were allowed the privilege of this examination each year. They represent men from every state in the country, in both urban and rural communities. The average age of the entire group was 47.8 years.

TABLE 1.—Symptoms Referred to the Heart in 2,400 Apparently Normal Males

Complaint	Group 1 (811, 33.8%)	Group 2 (1,339, 55.8%)	Group 3 (250, 10.4%)
	No Abnor- malities	Borderline Impair- ments	Definite Impair- ments
Pain around heart.....	1.7	4.0	5.2
Palpitation.....	0.9	1.0	2.8
Shortness of breath.....	1.4	1.7	3.2
Heartburn and pain in abdomen.....	2.8	2.7	1.6
Fear of heart disease.....	0.4	1.0	1.2
No symptoms.....	93.1	90.3	87.2

In this study the attempt to correlate habits and the results of physical examination with electrocardiographic changes has been made. Only the three conventional leads have been considered in the electrocardiogram.

The group of 2,400 has been divided into three classifications: first, those with normal electrocardiograms; second, those with borderline changes; and, third, those with definite impairments. We have con-

sidered borderline such electrocardiographic changes as low or iso-electric T₁ and T₂, left or right axis deviation, inverted or diphasic T₃, premature contractions, and depression of the RT segments of more than 1 mm. We have considered as definite impairments such changes as PR interval of more than 0.21 second, QRS interval more than 0.11 second, inverted or diphasic T₁, inverted or diphasic T₂, relatively deep Q₃, auricular fibrillation, or any combination of these. In group 1, that is, those which are normal, were found 33.8 per cent; in group 2, the borderline, 55.8 per cent; and in group 3, those with definite impairments, 10.4 per cent.

The various complaints of the individual at the time of examination were carefully noted and are listed in table 1. Among these were listed precordial distress of any kind, palpitation, dyspnea of even the slightest degree and abdominal pain. Also included among those

TABLE 2.—Percentage Incidence of Abnormalities and Habits of 2,400 Males, Grouped According to the Seriousness of Electrocardiographic Changes

Complaint	Group 1 (811, 33.8%)	Group 2 (1,339, 55.8%)	Group 3 (250, 10.4%)
	No Abnor- malities	Borderline Impair- ments	Definite Impair- ments
Weight			
Overweight 10% or more.....	24.5	45.7	46.4
Underweight 10% or more.....	6.9	2.0	1.6
Cardiac enlargement.....	1.0	3.0	9.2
Heart murmurs			
Systolic.....	4.8	6.0	10.4
Diastolic.....	0.1	0.1	1.6
Blood pressure			
Systolic 150 mm. or more.....	3.4	9.9	19.6
Diastolic 100 mm. or more.....	2.1	6.3	14.8
Occupation—executive.....	67.7	70.7	72.0
Habits			
Users of tea.....	26.0	31.6	36.8
Users of coffee.....	82.5	79.5	80.8
Users of alcohol.....	76.0	71.7	71.5
Recreation			
Sedentary hobbies.....	5.4	5.6	4.8
Moderate exercise.....	55.5	53.2	52.0
Strenuous exercise.....	16.0	11.6	6.8
History of heart disease in family.....	16.3	16.6	17.2
Average age.....	45.8	48.5	50.8

with complaints was any person who mentioned that he was at all heart conscious or had any fear of heart disease. In group 1, 93.1 per cent had no complaints. In group 2, 90.3 per cent had no complaints. In group 3, 87.2 per cent had no complaints. It is to be remembered, however, that these people came for a periodic health examination and not necessarily because they were ill. It is interesting to note that only 12.8 per cent of those who had serious impairments gave any symptoms that could be at all referable to the heart.

In table 2 is an attempted correlation of the various observations from the physical examination with electrocardiographic changes. The most significant factor noted was the prevalence of overweight in group 3. In group 1, 24.5 per cent were more than 10 per cent overweight, while in group 3, 46.4 per cent were overweight. In group 1, 6.9 per cent were underweight and, in group 3, 1.6 per cent were underweight. Thus, overweight is found approximately twice as frequently in group 3 as in group 1.

Enlargement of the heart as determined by palpation and percussion was found present in only 1 per cent of group 1 and 9.2 per cent of group 3. This is very striking.

Systolic murmurs were heard in 4.8 per cent of group 1 and 10.4 per cent of group 3, a very substantial increase.

The study of blood pressure seemed particularly significant. In group 1 there were 3.4 per cent who had a systolic pressure of more than 150 mm. In group 3 there were 19.6 per cent who had a systolic pressure of more than 150 mm. In group 1 there were 2.1 per cent who had a diastolic pressure of more than 100 mm. In group 3 there were 14.8 per cent who had a diastolic pressure greater than 100 mm. This indicates that hypertension was more than six times as prevalent in group 3 as in the normal group.

TABLE 3.—*Electrocardiographic Impairments in Various Blood Pressure Groups*

Diastolic Blood Pressure	(2,400) Number in Group	Group 1 (811, 33.8%) No Abnormalities	Group 2 (1,339, 55.8%) Borderline Impairments	Group 3 (250, 10.4%) Definite Impairments
Less than 70.....	305	46.6	41.6	11.8
From 70 to 79.....	818	40.0	52.4	7.6
From 80 to 89.....	820	22.0	38.3	9.8
From 90 to 99.....	369	19.1	69.9	11.0
100 or more.....	138	12.3	60.0	26.8

In order to throw further light on the relationship of blood pressure to electrocardiographic changes, the cases included in groups 1 and 3 were divided into those whose diastolic pressures fell between 70 and 80, 80 and 90, 90 and 100 and over 100 mm. This is shown in table 3. A very significant increase was noted in those who fell in group 3 as the diastolic pressures increased. Of those whose diastolic pressures were between 70 and 80 mm., 40 per cent were in group 1 and 7.6 per cent were in group 3; diastolic pressures 80 to 90 mm., 32 per cent were in group 1 and 9.8 per cent in group 3; diastolic pressures 90 to 100 mm., 19.1 per cent were in group 1 and 11 per cent in group 3; those with 100 mm. or more, 12.3 per cent were in group 1 and 26.8 per cent

the laboring group. Of the total group 69.9 per cent were classed as executive. In group 1, 67.7 per cent were executive. In group 3, 72 per cent were executive. In studying habits it was found that 26 per cent of group 1 were tea drinkers and 36.8 per cent of group 3 used tea; 82.5 per cent of group 1 were coffee drinkers and 80.8 per cent of group 3 were coffee drinkers; 76

Fig. 2.—A man aged 48, a manufacturer; No subjective symptoms; physical examination negative except for systolic hypertension (184/86). The electrocardiogram shows regular sinus rhythm, right axis deviation, notching and spreading of QRS. A definite tendency to low voltage of QRS also is shown.

per cent of group 1 used alcohol and 71.5 per cent of group 3 drank alcoholic beverages.

In studying recreation and exercise it was found that 5.4 per cent of group 1 were admittedly sedentary, 55.5 per cent did moderate exercising and 16 per cent did strenuous exercising. In group 3, 4.8 per cent were sedentary, 52 per cent moderate and 8.8 per cent strenuous. Again there were no significant differences.

TABLE 4.—*Percentage Incidence of Definite Electrocardiogram Impairments Among Smokers and Nonsmokers (812 Males)*

Condition	Nonsmokers (339)	Smokers (473)
Inverted or diphasic T ₁ and T ₂	0.3	0.8
Auricular fibrillation.....	0.3	..
PR interval 0.21 second or more.....	1.2	1.1
QRS duration 0.11 second or more.....	0.6	2.5
Low or iso-electric T ₁ and T ₂	1.5	2.1
Inverted or diphasic T ₁	1.2	1.3
Inverted or diphasic T ₂	0.8
Relatively deep Q ₃	2.1	2.7
Low voltage QRS (less than 5 mm.).....	0.9	1.5
Total with definite impairments.....	7.4	11.6

The effect of smoking on either the development or the course of coronary heart disease has been much discussed for many years. In order to throw some more light on this problem two groups were taken from the series: those who had never used tobacco and those who admitted to smoking continuously for more than ten years. The results are presented in table 4. There were 339 nonsmokers and 473 who had smoked for more than ten years. Of the nonsmokers 7.4 per cent were found in group 3. Of those who had smoked for more than ten years there were found 11.6 per cent in group 3. Thus there is approximately a 50 per cent increase in the incidence of definitely abnormal electrocardiographic changes in the smoker as compared with the nonsmoker. This becomes more striking since the nonsmokers were an older group whose average age

Fig. 1.—A man aged 48, a salesman; No subjective symptoms; negative physical examination. The electrocardiogram shows regular sinus rhythm and inversion of the T wave in the third lead. Q₃ is relatively deep.

were in group 3. Thus there is a steady increase from 7.6 per cent in group 3 for those with diastolic pressures between 70 and 80 mm. to 26.8 per cent for those having a diastolic pressure of more than 100 mm.

Occupation has always been considered a very important factor in the development of coronary heart disease. Unfortunately, this series is somewhat selective in that each person involved had more than \$25,000 of life insurance and consequently few, if any, were of

was 48.5 as compared with 47 years for the smokers, and the incidence of overweight was slightly higher in the nonsmoking group. The most striking abnormality noted in studying these two groups was an increased QRS duration. We found this to be increased more than four times as often in the smokers as in the nonsmokers. This comparison of smokers and nonsmokers would seem to indicate that smoking does play some part in the subsequent development of abnormal electrocardiographic changes.

With regard to the history of heart disease in either father or mother, 16.5 per cent of group 1 gave a positive history and 17.2 per cent of group 3 gave a similar history. From this study a history of heart disease in either father or mother had little influence on the incidence of electrocardiographic observations.

SUMMARY

1. In conjunction with physical examinations, complaints and habits, 2,400 electrocardiograms were studied. Of these 33.8 per cent were normal, 55.8 per cent were borderline and 10.4 per cent were definitely abnormal.

2. In the abnormal group 87.2 per cent were entirely symptom free.

3. Overweight was found to be twice as frequent in the abnormal group as in the normal group.

4. Enlargement of the heart was found to be nine times as frequent in the abnormal group.

5. Systolic murmurs were found twice as frequently in the abnormal group.

6. Systolic hypertension was found six times as frequently in the abnormal group.

7. Diastolic hypertension was found seven times as frequently in the abnormal group.

Fig. 3.—A man aged 46, an executive; No subjective symptoms; negative physical examination. The electrocardiogram shows regular sinus rhythm and low voltage of QRS. Qs is prominent and Ts slightly inverted.

8. There was no significant difference between the two groups so far as habits of tea drinking, coffee drinking or alcohol consumption was concerned.

9. There was a 50 per cent increase in abnormal electrocardiographic observations among the group of smokers as compared with the nonsmokers.

10. With regard to the parental history of heart disease there was no significant difference between the two groups.

11 East Forty-Fourth Street.

COMPENSATION FOR INDUSTRIAL INJURIES AND OCCUPATIONAL DISEASES

SOME LEGAL AND MEDICOLEGAL ASPECTS

E. RANSOM KOONTZ, M.D.

CHICAGO

The legal and medicolegal aspects of laws, state and federal, providing compensation for industrial injuries and occupational diseases are of great importance to physicians because of the broad scope and rapid expansion of industrial medicine as a phase of medical practice. Obviously, not all of the innumerable legal and medicolegal aspects of these laws can be presented here. A few of particular interest to the medical profession will be discussed.

COMPENSABILITY OF INDUSTRIAL INJURIES

The first comprehensive national scheme for providing compensation to injured workmen was established in Germany in 1884. It was not until 1902 that a workmen's compensation law was enacted in this country. In that year Maryland enacted such a law, which applied only to certain occupations, but it was later declared unconstitutional. In 1908 a federal compensation law, applicable only to the relatively few employees of the United States government engaged in hazardous occupations, was enacted and became effective August 1 of that year. Since that time all of the forty-eight states except Mississippi and Arkansas have enacted and placed in operation laws providing compensation to workmen for industrial injuries. In Arkansas a compensation law has been enacted, but its operation is suspended pending the outcome of a referendum which will be held in November 1940. In addition to state laws there are also federal compensation laws which apply to designated groups, such as civil employees of the United States government, longshoremen and harbor workers, workmen in the District of Columbia, and others. The federal government has also enacted workmen's compensation laws for Alaska, Hawaii and Puerto Rico.

Workmen's compensation laws may be compulsory or elective as to all employments covered or they may be compulsory as to some occupations and elective as to others. Compensation is compulsory for all or some private employments covered by the workmen's compensation acts in eighteen states and the District of Columbia and compulsory for all or some public employments covered in thirty-one states and the District of Columbia.¹ Compensation is elective as to all private employments affected in twenty-nine states and elective as to all public employments covered in fourteen states.² Where the right of election exists, it is commonly provided that if no election is made the three common law defenses are no longer available to the employer, namely assumption of risk, contributory negligence and the fellow-servant doctrine.

Workmen's compensation acts are commonly administered by agencies variously designated as workmen's compensation boards, commissions, bureaus, departments or commissioners. In Alaska and in six states, Alabama, Louisiana, New Hampshire, New Mexico,

From the Bureau of Legal Medicine and Legislation, American Medical Association.

1. Digest of Workmen's Compensation Laws of the United States and Territories, ed. 16, Association of Casualty and Surety Executives, 60 John Street, New York, 1939, p. 9.

2. Digest of Workmen's Compensation Laws, p. 10.

Tennessee and Wyoming, the laws are administered by courts, but even in these jurisdictions the operations of the laws are to some extent supervised or administered by designated administrative officials. In Connecticut there is a single commissioner in and for each of five autonomous districts. The workmen's compensation act of New York in some respects is administered by a single commissioner but in other respects it is carried out by an industrial board. Presumably hearings before the various administrative agencies or boards

only to certain stated hazardous or extrahazardous employments. Agricultural employments and domestic service are commonly exempted. Often it is provided that exempted employments may be brought under the act by election. In at least five states, Arkansas, California, Georgia, Idaho and New York, charitable organizations also are exempted. A waiting period after injury, varying from three days to two weeks, during which compensation is not to be paid, is usually provided.

Table is based on data in table entitled "Occupational Diseases Covered," Digest of Workmen's Compensation Laws of the United States and Territories, ed. 16, Association of Casualty and Surety Executives, 60 John Street, New York, 1939, page 14; Chart V, "Workmen's Compensation: Occupational Disease," as of Jan. 1, 1938, Division of Labor Statistics, U. S. Department of Labor; and data in files of Bureau of Legal Medicine and Legislation, American Medical Association.

1. Operation of law, enacted by state legislature providing compensation for industrial injuries and occupational diseases, is suspended pending outcome of referendum.
 2. In these four states, occupational diseases are compensable under occupational disease acts separate from workmen's compensation acts. Other than in these four states, the data presented in this table relate to workmen's compensation acts or amendments to such acts.
 3. Many of the laws which are designated as specifically providing compensation for silicosis also provide compensation for other occupational dust diseases, such as asbestosis.
 4. Laws which provide compensation for silicosis but do not specifically mention silicosis may also be considered as providing compensation for silicosis and other occupational dust diseases.
 5. Law covers "injuries," inclusive of occupational diseases.
 6. Law covers "occupational disease or infection" undefined, arising naturally out of employment or resulting from accidental injury.
 7. Only occupational disease covered is silicosis. The Kentucky law covers only silicosis in employees engaged in glass manufacturing, quarries and sand mines or in manufacturing, treating or handling sand.
 8. Law covers silicosis in mining only.
 9. Law covers occupational diseases undefined, subject to joint election of employer and employee.
 10. Only occupational diseases covered are those in smelting, metal refining and battery manufacturing industries.
 11. Law can be considered as covering only silicosis if it occurs in certain industries. See footnote 10.
 12. Law contains a schedule but with an additional paragraph covering "any and all occupational diseases" undefined. The New York Court of Appeals in *Goldberg v. 954 Marcy Corporation* (N. Y.), 12 N. E. (2d) 311 defined what is meant by "any and all occupational diseases."
 13. Law covers any disease "approximately" caused by employment.
 14. Law contains a schedule but with an additional paragraph covering "all other occupational diseases" in general terms.
 15. Law covers "harm" caused by accident or disease.
 16. Law covers disease proximately caused by or resulting from nature of employment.
- In addition, occupational diseases specifically described or scheduled are compensable in Puerto Rico and occupational diseases undefined are compensable in Hawaii.

were designed to be simple and informal, but actually in many jurisdictions today there is little difference between a controversy before such an agency and litigation before a court of law. The determinations of these administrative agencies are not final but may be appealed to the courts. However, the findings of these boards as to facts, if such are sufficient in law, are final.

The scope of laws providing compensation for industrial injuries differs so widely that it is well nigh hopeless to attempt classification. Some of these laws apply to all employments in which more than a designated number of workers, varying from two to sixteen, are employed. Other acts apply primarily or unqualifiedly

What conditions are compensable, that is, what constitutes a compensable industrial injury or accidental injury, will depend on the language of the workmen's compensation law in each particular jurisdiction. The majority of these laws by their terms require that the injury be accidental, that is, unexpected or unforeseen. There is a tendency, however, by amendment of the acts or by court interpretation not to require that the injury be accidental to be compensable. In most of the states the act covers only injuries "arising out of and in the course of" employment; in a few states, North Dakota, Pennsylvania, Texas and Washington, the law covers injuries incurred "in the course of" employment, and in

Utah the law covers injuries "arising out of or in the course of" employment. The acts of California, Iowa and Massachusetts cover "injuries," the term being not defined. The Wisconsin act covers mental or physical harm caused by accident or disease. The North Dakota act covers injuries by accident and any disease "approximately caused by" employment. In a few states, as in Pennsylvania and Texas, a compensable injury is defined to mean damage or harm to the physical structure of the body and such diseases or infection as naturally result therefrom. Even in the absence of such a definition, under most of the acts compensation is allowed for such diseases as naturally follow from

pensable as an occupational disease. In nine states the acts contain special provisions relating to malpractice by attending physicians.

COMPENSABILITY OF OCCUPATIONAL DISEASES

Just as a workman should receive compensation for an injury which he sustains in the course of his employment, to compensate him in some way for his loss, so also should a workman receive compensation for a disease which he contracts as the result of conditions of his employment. More and more jurisdictions are enacting laws which provide compensation for occupational diseases. Today, twenty-four states provide com-

Table is based on data in table 7, "Maximum Periods and Amounts of Medical Service, by States," Monthly Labor Review, vol. 47, p. 553, September 1938, supplemented by data in files of Bureau of Legal Medicine and Legislation, American Medical Association.

1. Additional service may be given at option of employer.
2. Employees contribute.
3. Additional service in special cases or at discretion of commission.
4. Operation of law, enacted by state legislature providing compensation for industrial injuries and occupational diseases, is suspended pending outcome of referendum.
5. In case of disability resulting from inhalation of harmful dust, period of treatment is limited to 270 days.
6. Medical or other treatment for asbestosis or silicosis shall be limited to three years and a maximum cost of \$334 a year.
7. In case of hernia, if employee requires operation he is entitled to service without limitation of time.
8. In surgical cases maximum may be increased by order of commission to \$500.
9. Amount is exclusive of hospital treatment and artificial appliances.
10. In case of employee receiving hospital treatment for more than fourteen days, the maximum is \$250.
11. Hospital services may be extended for an additional two weeks on certification of attending physician as to necessity.
12. Also hospital first thirty days, maximum \$150.
13. Extended in unusual cases. Not to exceed 180 days.
14. In case of temporary disability, continues not longer than period of compensation, and in case of permanent disability not beyond the date of award. Employees contribute.
15. Interpreted as unlimited by Wisconsin Industrial commission.
16. Additional expenditure of not more than \$150 for medical service and \$150 for hospital treatment may be authorized by court.
17. A special operating fee of \$100 allowed in case of hernia.

an industrial injury. Aggravation of a preexisting disease by injury is usually considered an industrial injury and not an occupational disease. In Connecticut and Florida disability or death due to the aggravation or the acceleration of venereal diseases is not compensable.

Courts have not infrequently allowed compensation, under workmen's compensation acts which make industrial injuries compensable, for conditions, such as lead poisoning, which actually are "occupational diseases." The laws in twenty-five states contain special provisions relating to hernia. A workman suffering from a hernia is required in some states to submit to surgical repair. In many of these twenty-five states the laws specifically define what constitutes a compensable hernia. In Michigan and Rhode Island a hernia sustained in the course of employment is not an accidental injury but is com-

pensation for such diseases. The federal government also allows compensation for such diseases in the District of Columbia and under its compensation laws relating to longshoremen and harbor workers and civil employees of the United States.

As in the case of industrial injuries, compensation for occupational diseases may be compulsory or elective. Likewise the federal laws and most of the state laws providing compensation for occupational diseases are administered by boards, commissions, bureaus, departments or commissioners. In Connecticut there is a single commissioner in and for each of five autonomous districts. In New York the law in some respects is administered by a single commissioner but in other respects by an industrial board. The determinations of these administrative agencies are not final and are always appealable to the courts.

In four states, Idaho, Illinois, Indiana and Pennsylvania, occupational diseases are made compensable under special occupational disease acts which are separate and apart from the workmen's compensation acts of those states. In all of the other jurisdictions which provide compensation for occupational diseases, compensation is based on statutory provisions in workmen's compensation acts or judicial interpretation of such acts. Detailed information relative to the compensability of occupational diseases is set forth in table 1.

An examination of table 1 reveals that fourteen states provide compensation for occupational diseases by specifically describing or enumerating in a schedule the diseases that are covered. Such a schedule may be composed of only a few diseases or it may consist of a large number. In two more states, New York and Ohio, the laws cover a schedule of diseases and "any and all occupational diseases" or "all other occupational diseases" respectively. In all other jurisdictions in which occupational diseases are compensable, including eight states and the District of Columbia, the law covers "occupational diseases" in a general or blanket manner either by defining "occupational disease" in general terms or, for all practical purposes, not defining it at all. In some of the states only occupational diseases occurring in certain designated industries are covered. Most of the laws providing compensation for occupational diseases, either by specific or by general language, may be said also to allow compensation for silicosis and, in many instances, other occupational dust diseases.

To define an occupational disease has proved most difficult. Where a schedule is resorted to, obviously the list of diseases adopted is not likely to be all inclusive and so revisions from time to time will become necessary. One of the better attempts to define an "occupational disease" in general terms is that to be found in the definition of that term in the Illinois occupational disease act, which is as follows:

In this Act the term "Occupational Disease" means a disease arising out of and in the course of the employment. Ordinary diseases of life to which the general public is exposed outside of the employment shall not be compensable, except where the said diseases follow as an incident of an occupational disease as defined in this section.

A disease shall be deemed to arise out of the employment, only if there is apparent to the rational mind upon consideration of all the circumstances, a direct causal connection between the conditions under which the work is performed and the occupational disease, and which can be seen to have followed as a natural incident of the work as a result of the exposure occasioned by the nature of the employment and which can be fairly traced to the employment as the proximate cause, and which does not come from a hazard to which workmen would have been equally exposed outside of the employment. The disease must be incidental to the character of the business and not independent of the relation of employer and employee. The disease need not to have been foreseen or expected but after its contraction it must appear to have had its origin in a risk connected with the employment and to have flowed from that source as a rational consequence.³

This definition was incorporated in the occupational disease act of Indiana. The statutory definitions of "occupational disease" at best are none too clear. If no attempt is made in the law to provide a schedule of diseases or to define an "occupational disease," then it is up to the courts to define what is meant by that

phrase. Here again the results have been none too satisfactory. Consequently there is today in many of the states no clearcut legal distinction between "occupational diseases" and "industrial injuries."

MEDICAL AND HOSPITAL BENEFITS

Medical and hospital services which employers or their insurance carriers are required to furnish to industrially injured or occupationally diseased employees constitute the most significant phase of compensation. It is estimated that three fourths of industrial injuries do not involve disability over a sufficiently long period to require cash compensation but that most of these require medical attention and perhaps hospitalization.

All of the laws which provide compensation for industrial injuries or occupational diseases require the employer, or his insurance carrier, to furnish or be financially responsible for, frequently within certain limitations, necessary medical and hospital services to industrially injured or diseased workmen. Most of these laws fix certain maximum limitations, as to time or to cost or to both, beyond which medical or hospital services need not be furnished by the employer or his insurance carrier. A minority of these laws, however, impose no maximum limitation as to either time or cost. While the law may not impose specific limitations and so the medical and hospital care which the employer or his insurance carrier must furnish may be said to be "unlimited," yet such services are subject to this limitation that they must be reasonable, that is, only such as the nature of the injury or condition reasonably requires. In some of the laws, as in Arizona and North Dakota, a limitation of reasonableness is specifically provided. In a few states medical and hospital benefits are limited to the period of disability or period of compensation. Even where limitations exist, commonly provision is made for the administrative agency to remove the limitations, at least in individual cases or unusual cases, and order further treatment or hospitalization either without limit or not beyond an additional limit set forth in the statute.

The maximum limitations imposed as to medical and hospital benefits in compensable industrial injuries are set forth in table 2. There is a definite tendency, especially in recent years, for legislatures to liberalize the provisions in workmen's compensation laws relating to medical and hospital benefits either by abolishing limitations as to time or to cost or to both or by raising the maximum limitation or limitations provided.

The maximum limitations imposed on medical and hospital services which employers or their insurance carriers are required to furnish in compensable occupational diseases are presented in table 3. In three states, Illinois, New York and North Carolina, limitations as to time or cost or both apply only to cases of silicosis or other occupational dust diseases.

FREE CHOICE OF PHYSICIAN

Under the earliest workmen's compensation acts, free choice of physician by an injured workman, except at his own cost, was seldom permitted. In later years there has been a trend toward free choice both in statutory amendments and in administrative practice. In spite of this trend, under federal compensation laws and the laws of most states the employer or insurance carrier or insurance fund still has the right to choose the physician or hospital. In such jurisdictions the industrially injured or occupationally sick worker, if he

3. Smith-Hurd Illinois Annotated Statutes, 1939, ch. 48, sec. 172.6.

desires to be treated free of cost to himself, must accept the physician, hospital or nurse, regardless of competence, tendered by the employer or the employer's insurer. In an emergency, however, the workman may choose his own physician or hospital. Of course, the worker may always choose his physician without cost to himself whenever the employer or his insurance carrier refuses, on demand, to furnish necessary medical or hospital services. The employee may always be treated by a physician of his own choosing at his own expense, but that can hardly be said to be any free choice of physician. In such jurisdictions the employers or insurance carriers may of their own initiative prepare panels of physicians from which the employee may select a physician.

According to the files of the Bureau of Legal Medicine and Legislation, the employee has the right to select a physician of his own choice in comparatively few of the states. In Massachusetts and Rhode Island the worker has the right unconditionally to select a physician of his own choosing. In Minnesota the workmen's compensation act has been construed to permit the worker to select his own physician, although the language of the act is similar to that of other state acts which have been construed as denying free choice. In Utah the law provides that the employee may select his own physician, unless the employer has arranged for medical services by contract and has posted such contract in and about the premises where the workman is employed. This act has also been construed to give the worker the right of selection. In North Carolina and Vermont the employee may select a physician of his own choosing subject to the approval of the workmen's compensation board. In three states, Wisconsin, California and New York, the worker may select his physician from a panel or list of physicians. In Wisconsin the employee has the right to select his physician from a panel prepared and posted by the employer. In California the law requires the employer to tender the employee on his request one change of physicians and to nominate at least three additional competent physicians, or as many as may be available if three cannot reasonably be named, from whom the employee may choose. Also the employee is entitled, on request, to a consulting physician to be provided by the employer in any serious case. In New York the employee may select his physician from a panel or list of physicians, approved and authorized by the state industrial board to render medical care to injured or sick workmen. However, the industrial commissioner is required, on the recommendation of any county medical society or of a board representing physicians of any other school of medical practice, to authorize physicians licensed to practice medicine in the state to render such medical care. The New York law thus almost entirely places on the local medical societies the responsibility for the quality of medical care. In Connecticut and Nebraska, while the employer has the right to designate the physician in the first instance, in all cases involving dismemberment or a major surgical operation the employee may designate the operating surgeon. A workman in Pennsylvania, after petition to the workmen's compensation board and notice to his employer, may consult a physician of his own choice at any time during his disability, the cost of such consultation to be paid by the employer in accordance with the schedule of charges prescribed and approved by the board. Although it is possible that administrative boards in a few states,

by administrative ruling, may permit employees to select physicians of their own choosing, no discussion of such administrative practice will be presented here.

The right of an industrially injured or occupationally sick workman to choose the physician who shall treat him is a highly controversial subject. The real question involved is How can competent medical service best be obtained? It is a fundamental principle of medical ethics that the patient, if he is to have adequate medical care, shall have free choice in selecting his physician. The argument sometimes advanced that a workman is unable to make a good choice of a physician to treat him, while perhaps true in some cases, overlooks the fact that the workman's vital interest in the

preservation of his health and earning capacity and prolongation of his life is a supreme inducement to a wise choice of an attending physician. The contention that employers are better able to judge the qualifications of physicians than are their employees might have some force were all employers conscientious, high minded and well meaning persons interested in the welfare of their employees and experienced in selecting competent physicians. While it is probably true that during the last ten or twenty years many employers have swung from cheap inadequate medical service to good medical service, no matter what the cost, because they have learned that cheap medical service in the long run is

expensive medical service, it must be remembered that compensation laws apply to all types of employers and to industries in the sparsely populated areas as well as in the metropolitan centers. Also the majority of industries depend on insurance companies to supply the medical and hospital care required. An employer interested in the welfare of his workmen should realize that, where employees are allowed to choose between the medical service established by the employer in his plant and the medical service obtainable elsewhere, a healthy competition is stimulated between his own physicians and those on the outside. It should not be overlooked that absolute denial to the employee of the right to choose his

questions of a purely medical nature should be passed on by those who have met the standards of medical qualifications required by law and who alone have been pronounced capable of passing on such questions.⁴

According to Marshall Dawson,⁵ of the Bureau of Labor Statistics of the U. S. Department of Labor, as of Jan. 1, 1938, in twenty-one states the workmen's compensation authority had a medical staff, but with full-time officers in only eight instances. He further states that most of the industrial commissions, in case of medical dispute or apparent prejudice, have authority to select an independent physician to examine the worker, but in several instances commissions reported

Table is based on data in chart V, "Workmen's Compensation: Occupational Disease," as of Jan. 1, 1938, Division of Labor Statistics, U. S. Department of Labor, supplemented by data in files of Bureau of Legal Medicine and Legislation, American Medical Association.

1. Operation of law, enacted by state legislature providing compensation for industrial injuries and occupational diseases, is suspended pending outcome of referendum.

own physician in that respect reduces the workman to the status of a machine or puppet in the hands of the employer or the employer's insurer. No injured workman should be denied the right to be treated by a physician of his own choice if he so desires.

ROLE OF PHYSICIANS IN ADMINISTRATION OF COMPENSATION LAWS

An agency administering laws providing compensation for industrial injuries or occupational diseases or both can hardly competently or efficiently make determinations involving medical aspects of compensation without representation on such administrative boards of doctors of medicine or without the aid of a medical board, medical advisers, medical consultants or impartial medical examiners. And yet many such agencies do just that. There should be medical representation proportionate to the medical interests involved, because

lack of funds to pay for examinations which they do not consider properly chargeable to the employer or insurance carrier. The methods provided for the determination of medical matters under laws providing compensation for occupational diseases are discussed in table 4.

REPORTING OF INDUSTRIAL INJURIES AND OCCUPATIONAL DISEASES

Laws providing compensation for industrial injuries and occupational diseases often specifically impose on physicians treating industrially injured or occupationally diseased workmen the duty to render reports usually on forms provided for that purpose, to the

4. Medical Relations Under Workmen's Compensation, Revised Report prepared by the Bureau of Medical Economics, American Medical Association, Chicago, 1935, ch. IX, p. 144.

5. Bureau of Labor Statistics Serial No. R. 867; Medical Aid to Workmen's Compensation Laws, United States Government Printing Office, Washington, D. C., 1939, p. 16.

workmen's compensation board or other administrative agency or to the employer or to both. Under some circumstances, physicians may be required by compensation laws to render reports to injured or sick employees. Aside from compensation laws, physicians are not infrequently required, by laws primarily relating to reporting of communicable diseases, to report occupational diseases to state boards or departments of health. Also the compensation laws of a large number of states require employers to report industrial injuries and occupational diseases to the workmen's compensation board or other administrative agency. Because the employer in rendering such reports must rely on physicians for details of injury and disease, it is not unlikely that the employer, by contract of employment or otherwise, will require industrial physicians to render reports to him. Under such circumstances the industrial physician should render such reports to the employer even though he is not required by law or by contract to do so.

For cogent reasons, all industrial injuries and occupational diseases should be required by law to be reported. Such reporting is necessary to prevent and control effectively such injuries and diseases as far as that is possible. Such reporting also furnishes valuable data for statistical and scientific purposes.

MEDICAL TESTIMONY IN COMPENSATION CASES

In any discussion of the legal and medicolegal aspects of compensation for industrial injuries and occupational diseases some mention should be made of the difficulty of obtaining reliable impartial medical testimony in compensation cases before workmen's compensation boards or before the courts. The medical profession, by medical opinions that are false or biased or founded on inadequate medical information and on possibilities rather than probabilities, has extended, more or less innocently, the scope of compensation. Uniform standards of evaluating injury or disease are urgently needed, as the American Medical Association has done with respect to appraisal of loss of visual efficiency. Better instruction in medical schools in industrial and legal medicine should do much to solve this problem.

Irrespective of the status or availability of accurate scientific information in the field of industrial medicine, medical testimony in compensation cases all too frequently is unreliable because of the medical witness himself. It is a most trying task for a medical witness to be absolutely unbiased and candid. To begin with, he is called to testify because his opinion is known to be favorable to the party calling him. If the medical witness was employed by the injured or diseased workman to treat him, he must be a man of great integrity to overcome the temptation to testify in such a manner as to help out the workman, especially since there may be financial gain to him if disability is prolonged. All too frequently, not only workmen and lawyers but also physicians attribute real or assumed pathologic conditions to trauma simply because such conditions appeared after an accident. This is not so strange when one recalls that in primitive times, long before the days of medicine, man because of his superstitious nature blamed external influences over which he had no control, such as gods, evil spirits and heavenly planets, for most of his bodily infirmities. Overreliance on medical and medicolegal textbooks is also responsible for some of the mistaken or unreliable medical testimony, because the authors too frequently round out their discussions

of the etiology of pathologic conditions by adding, without scientific justification, the words "and injuries" or "also due to injuries," statements which had been copied and recopied from predecessors of even decades before. On the other hand, if the medical witness was or is employed by the employer of the injured or diseased workman, many factors, economic and otherwise, likewise come into play to tend to influence his testimony and make it favorable to the contentions of the employer. Indeed, it requires a physician of stern conscience and rigid integrity to resist all these various influences and testify to the truth and nothing but the truth.

Untrustworthy medical testimony in compensation cases, which is due to the incompetence or fault of the medical witness himself, may be of four types: (1) Where the physician, because of ignorance or lack of proper preparation, makes an honest error; (2) where the physician is so emotionally disturbed as to become confused and makes honest mistakes; (3) where the physician dishonestly makes a guess instead of frankly confessing his lack of medical knowledge, and (4) where the physician, perhaps one biased by his employment but more frequently a so-called professional expert medical witness who makes his living by deliberately giving false expert medical testimony, testifies falsely. Lawyers and judges use the professional expert witness only when they have to, but they do not respect him. His position, while perhaps lucrative, is certainly an unsavory one. His conduct has brought discredit to the medical profession and has done much to make honest physicians shun the courts.

In compensation disputes tried before courts of law the competence of medical witnesses is primarily the responsibility of the judge as he is the one who passes on their qualifications. High standards of qualifications for medical witnesses should be set and compliance with those standards should be required. Close cooperation in the matter of qualifications of medical witnesses between courts and the medical profession through local medical societies would seem to make for more reliable medical testimony. The feasibility and possible advantages of laws specifically authorizing courts to appoint nonbiased medical boards, composed of duly licensed and qualified doctors of medicine, to pass on questions requiring medical knowledge, would seem to be a fertile field for study. Likewise, the advantages in disputes before workmen's compensation boards of establishing medical boards or medical advisers, as some states have already done, to pass on medical questions, such as the relation of disability to trauma and the evaluation of disability, also merit earnest deliberation.

This discussion has touched only a few of the many legal and medicolegal phases of compensation laws of prime importance to physicians interested in the field of industrial medicine.

535 North Dearborn Street.

A Day's Sport.—A man's hobby must be something which his soul loves. Nor is its value measured only by the hours spent in its indulgence, since no small part of its benefit comes from pleasurable anticipation of joys to come or happy memories of past triumphs. Such relaxations afford relief to restless brains at unexpected times. How often have I gone to bed with a mind jaded and sleepless from medical worries, when pleasant thoughts of a day's sport have wiped the slate clean and sent me into sound sleep.—Smith, Lewis, in *Doctors in Shirt Sleeves*, edited by Sir Henry Bashford, London, Kegan Paul, Trench, Trubner & Co., Ltd., 1939.

Clinical Notes, Suggestions and New Instruments

ROENTGENOLOGIC DEMONSTRATION OF LOCALIZED GAS IN CAISSON DISEASE

J. O. GORDON, M.D., AND C. H. HEACOCK, M.D.
MEMPHIS, TENN.

The condition caisson disease, described as compressed air disease and divers' paralysis and commonly spoken of by the laborers as "bends," has been known for a long time. It is generally regarded as being due to a saturation of the tissues with nitrogen gas, followed by too rapid decompression, which allows the escape of bubbles of nitrogen into the tissues and into the blood stream, causing air embolism.

The disease was first studied by the French writers Bucquay, Foley and Bert during the latter part of the nineteenth century. Since that time important contributions to the subject have been made by Leyden, Haldane, Hill, Boycott, Smith and others.

The disease is encountered chiefly among workers in caissons and tunnels and in divers. It may also occur in very deep mines. The higher the pressure and the shorter the period of decompression, the greater the risk of precipitating an attack.

During compression, the air passing to the lungs is saturated with nitrogen under pressure. The nitrogen is carried to the tissues until the entire body is saturated. It has been shown by Haldane and Smith that the blood is 5 per cent of the body weight. Haldane has also shown that approximately one minute is required for the blood to return to the heart. During compression the capacity of the blood to take up nitrogen increases approximately 1 per cent for each additional atmosphere of pressure. If every part of the body was equally supplied with blood and the blood was one twentieth of the body weight, theoretically saturation would be complete in twenty circulations. Actually this is not true. The blood returns to the heart each time with a saturation equal to that of the tissues. Thus each time its power to receive additional nitrogen is lessened. In addition, 20 per cent of the body is composed of fat and Vernon has shown that fat takes up five times more nitrogen than ordinary body fluids. Haldane has estimated that half saturation takes place in fifteen minutes and that almost an hour

Fig. 1.—Gas in synovial sacs about three hours after injury.

is required for complete saturation. Saturation becomes more rapid during labor, because of the increased speed of the circulation.

During decompression the action is the reverse of the process just described. Supersaturated tissues give off nitrogen to the blood, which is desaturated by the lungs. This process keeps up until atmospheric equilibrium has been reached. Should the decompression take place too rapidly to allow this desaturation, gas bubbles of nitrogen will form in the body fluids and tissues. This formation of gas bubbles is the accepted theory, at present,

of caisson disease. These bubbles form first in the arterial blood, fatty tissues, synovial fluids of the joints, and the nervous system.

The symptoms may vary from headache, dizziness and feeling faint to nausea and vomiting or, in extreme cases, coma followed by death in a few hours. There is severe pain, usually in the legs and in the abdomen. Paralysis is rather common and usually transitory in the slight cases. Late changes are injury of the spinal cord, chronic arthritis and deafness.

Prophylaxis consists solely in gradual decompression and regulation of the shifts. It was early found that immediate recompression was the best remedy. Workers should live and

Fig. 2.—Resorption of gas six weeks later.

sleep near the works, where an air-lock is provided for immediate treatment. The inhalation of oxygen, under pressure, has been shown to reduce the partial increased pressure of nitrogen in the blood and thereby increase absorption of nitrogen by the blood. Morphine is frequently required for relief of pain, and in extreme cases circulatory stimulants are required along with the usual treatment for shock.

REPORT OF CASE

P. D., a white man, aged 30, employed as a tunnel worker, was admitted to St. Joseph Hospital, Memphis, Tenn., Nov. 19, 1938, complaining of severe pains in both lower extremities. Just prior to admission, while working in a tunnel, he was struck across both legs at about the level of the knee joints by a loaded "dinky tunnel car" as it overturned. He was working under 25 pounds of pressure at the time of the accident. Because of severe pain he was removed from the tunnel without spending the customary time in the decompression chamber. He gave a history of having been employed as a tunnel worker for six years and had on several previous occasions had "bends." There had been an injury to the right ankle in 1936.

On admission to the hospital at 2 a. m. he was seen by Dr. J. C. Ayres Jr., the associate of one of us (J. O. G.). He was complaining of severe pain in both knees and thighs. Because of the confusion and haste incident to removing him from the tunnel and bringing him to the hospital, he could not state definitely whether the pain immediately followed the accident or not. Later in the morning he stated that the severe lancinating pains were the same as he had experienced on previous occasions when he had had attacks of the "bends." More morphine was required to control his pain than is usual in fractures of the tibia. He did not complain of headache, dizziness or nausea.

Immediately after admission he was taken to the roentgenologic department for examination of both knees. This examination revealed irregular linear fractures of the upper ends of the tibias of both legs. On the right side the line of fracture involved the articular surface of the knee joint. There was no gross deformity or displacement of the fragments at either site. There was gas in the synovial sacs of both knees. This was believed to be due to the rapid expansion of the nitrogen molecules in the blood stream and the escape of this gas into the capsule (fig. 1).

At the physical examination the patient complained of severe pain in both legs at the level of the knee joints. This was aggravated by the slightest motion and by superficial palpation. There was swelling and ecchymosis about both knees and crepitus was easily elicited. Otherwise the examination was negative.

After the roentgenologic examination, Thomas splints were applied to both legs and morphine sulfate one-fourth grain (0.016 Gm.) was given for the pain. Urinalysis showed a trace of albumin and a few pus cells and bacteria. There were 14,250 white blood cells with 77 per cent polymorphonuclear leukocytes and 33 per cent lymphocytes.

The day following admission, plaster casts were applied from the mid thigh down. Convalescence was uneventful from this time on, and a check-up x-ray examination on December 29 (fig. 2) showed the fragments of both tibias in good position. Bony union was fairly firm. All the gas in the synovial sacs had been absorbed and apparently there had been no permanent injury to the joints. The patient was discharged from the hospital Jan. 7, 1939, and he returned to work exactly twelve weeks after the injury.

We have been unable to find any mention of a case in the literature in which the diagnosis was supported by x-ray examination.

1418 Exchange Building.

LEATHER BUFFERS' NODES

LEON H. WARREN, M.D., WASHINGTON, D. C.

Bernardino Ramazzini first called attention to the value of recognizing trade stigmas in the diagnosis of occupational dermatoses. Although many of the stigmas since recorded are merely fortuitous lesions which do not affect all or even a majority of workers in a trade, the stigma reported in this article affected each of the eleven workers employed at hand buffing of leather in a large tannery investigated. This stigma occurs at a constant site, is always bilateral and is characteristic.

The hand buffing of leather is a highly specialized but fast disappearing craft. Now that machines are replacing hand labor in this operation there are not more than fifty of these craftsmen remaining in the United States. These workers move from one tannery to another to supply temporary demands for their

Fig. 1.—Thumbs of three hand buffers.

services in the buffing of certain types of leather. This operation is necessary for the removal of briar scratches, wire fence scratches, manure grain, tick bites and fly bites. The types of leather which require hand buffing are retan, harness, horse collar and horse butts, from which genuine cordovan leather is prepared. Hand buffers constitute a pseudoguild into which few apprentices are taken. Formerly the hand buffer came to work in frock coat and topper and was the aristocrat of the

From the Office of Dermatoses Investigations, United States Public Health Service, Medical Director Louis Schwartz in charge.

tannery workers. Even now, hand buffers work shorter hours than other tannery workers and limit their output to a certain number of sides (hides) daily.

Buffers' nodes, or calluses, as they are called by the workers, are a transient stigma as contrasted with permanent stigmas. When the worker goes on a month's vacation much of the node

Fig. 2.—Process of hand buffing leather.

disappears. On his returning to work, until a new callus forms the site is again painful on rubbing, just as it was when the buffer was serving his apprenticeship. About three weeks is required for the development of a nonsensitive node.

The lesions are bilateral and occupy the major portion of the dorsal surface of the distal phalanx of the first digits of each hand. The individual node is round to oval, approximately from 1.5 to 2 cm. in diameter and 6 mm. in thickness. Figure 1 is the reproduction of a close-up photograph of the thumbs of three hand buffers.

In the operation of hand buffing the worker grasps a knife, known as a buffing slicker, having a cornuate wooden handle and a thin rectangular steel blade approximately 4 inches by 6 inches by $\frac{1}{8}$ inch (10 by 15 by 0.3 cm.). The edge of the slicker is hollow ground and must be sharpened by running a long thin round file along its edge. This knack is both difficult to acquire and difficult to retain. Some of the workers lose the knack either temporarily or permanently and must then have a fellow worker sharpen the blade.

The hand buffer grasps the slicker with the thumbs under and the other fingers of each hand over the steel blade. The palmar surfaces of the hands are pronated on the uppermost surface of the slicker. The nodes which constitute the hand buffers' stigma result from the necessity of having the thumbs slide firmly over the surface of the leather in order to gauge the depth to which the buffing slicker shaves. Figure 2 illustrates the process of hand buffing leather and exhibits a thinly shaved ribbon which has been partially removed by a stroke of the slicker.

SUMMARY

During the buffing of hides, characteristic bilateral calluses invariably develop on the dorsum of the thumbs of leather buffers as a result of friction.

Council on Physical Therapy

THE COUNCIL ON PHYSICAL THERAPY HAS AUTHORIZED PUBLICATION OF THE FOLLOWING REPORT.

HOWARD A. CARTER, Secretary.

DRINKER-COLLINS ADULT RESPIRATOR ACCEPTABLE

Manufacturer: Warren E. Collins, Inc., 555 Huntington Avenue, Boston.

The Drinker-Collins Improved Adult Respirator is a device for producing artificial respiration simulating natural breathing for indefinite periods of time. A similar model has been accepted by the Council since 1931 (*THE JOURNAL*, May 9, 1931, p. 1580). Since that time certain improvements and changes have been made.

The unit functions by alternately producing a slightly sub-atmospheric and atmospheric (occasionally slightly positive) pressure in the chamber which encloses all the body except the head. The lungs are inflated during the negative pressure phase and passively deflated during the atmospheric pressure phase. The apparatus consists of a cylindric steel chamber mounted on a welded steel framework, which also supports the operating mechanism. The chamber contains a cot attached to the removable head-end closure. Casters on the legs of this closure and on the cot facilitate rolling the cot from the chamber for placing patients in the respirator. The respirator is mounted on casters so that it may be moved conveniently.

There are several models of this unit. In the Standard Model, the chamber is fixed in a horizontal position and is 28 inches in diameter throughout. In the Tilting-Rotating Model, means are provided for elevating the foot end of the chamber and tilting the cot toward either side to facilitate drainage of the respiratory tract. The Orthopedic Model embodies these features of the Tilting-Rotating Model and in addition is enlarged to a diameter of 42 inches at the head end, enabling use of "airplane splints" and other orthopedic appliances. In all models the interior length is 70 inches. Since the head is outside, persons up to about 6½ feet in height may be accommodated.

Drinker-Collins Adult
Respirator.

The net weight of the Standard Model is 470 pounds, of the Tilting-Rotating Model 540 pounds, and of the Orthopedic Model 760 pounds. Shipping weights (via Railway Express, wrapped but not crated) are 500, 570 and 800 pounds respectively, and by freight (boxed) 900, 970 and 1,300 pounds respectively.

The chamber of the unit is provided with five arm openings provided with sponge rubber diaphragms thus making possible

various operations inside the chamber without interference with the respiration of the patient. Easily closed covers seal the arm openings when not in use. A larger opening is provided for the insertion of bed clothing and other articles. Four observation windows are equipped with nonbreakable panes. Other features include a rubber-covered mattress, a protected light bulb to illuminate the interior and an adjustable head rest and sponge rubber collar.

The pump consists of a corrugated rubber "accordion" style bellows, actuated by levers from a heavy-duty worm reduction unit connected by a variable speed drive to a one-fourth horse power electric motor. The bellows may also be operated by hand. The range of operating speeds when the motor is in use is about 14 to 28 respirations per minute. The motor is furnished for alternating or direct current as specified. A recessed control panel is mounted on the side of the respirator and bears the switches for the motor and light, the diaphragm type dial pressure gage, a positive pressure control and an overall pressure control to regulate both negative and positive pressures. The power consumption depends on the pressure used and on the rate of respiration. Under normal conditions it averages 200 watts.

Questionnaires were sent out by the Council to physicians and hospitals listed by the firm as having had experience with the unit. Eighteen replies were received, giving favorable data on the efficiency and durability of the apparatus. All the reports cited experience with the apparatus of at least several years' duration and included many cases.

The unit was submitted to a qualified physician for the purpose of clinical trial. A summary of the results of the Council investigation is as follows:

In comparison with the earlier model of the respirator, the new model is lighter and more attractive in appearance and it is quieter in operation on account of substitution of the bellows for the metal pump. A change from the sixteen small clamps on the old model to three large clamps used when sealing the head and cot in position for operation is a great improvement. The elevator screw for adjusting the level of the patient's head is also a good device which was not present originally. The instrument panel is an added convenience. A metal bar provided for hand operation of the bellows in case there is failure of electric current is another new factor which might be of vital importance. There is no question that this new model respirator is a much better machine than its predecessors from the standpoint of design, operation and convenience in adjustment.

The Council on Physical Therapy voted to accept the Drinker-Collins Improved Adult Respirator for inclusion on the Council's list of accepted devices.

Council on Pharmacy and Chemistry

NEW AND NONOFFICIAL REMEDIES

THE FOLLOWING ADDITIONAL ARTICLES HAVE BEEN ACCEPTED AS FORMING TO THE RULES OF THE COUNCIL ON PHARMACY AND CHEMISTRY OF THE AMERICAN MEDICAL ASSOCIATION FOR ADMISSION TO NEW AND NONOFFICIAL REMEDIES. A COPY OF THE RULES ON WHICH THE COUNCIL BASES ITS ACTION WILL BE SENT ON APPLICATION.

PAUL NICHOLAS LEECH, Secretary.

LIQUID PETROLATUM (See New and Nonofficial Remedies, 1939, p. 300).

The following dosage forms have been accepted:

Emulsion Liquid Petrolatum, Chocolate Flavored: A palatable emulsion containing 60 per cent (by volume) of liquid petrolatum, 1 per cent agar agar per fluidounce and 0.1 per cent of benzoic acid added as preservative.

Prepared by the Smith-Dorsey Company, Lincoln, Neb. No U. S. patent or trademark.

Emulsion Liquid Petrolatum with 1½ grains Phenolphthalein per fluid ounce, Chocolate Flavored: A palatable emulsion containing 60 per cent (by volume) of liquid petrolatum, 0.097 Gm. (1½ grains) of phenolphthalein-U. S. P., 1 per cent of agar agar per fluidounce and 0.1 per cent of benzoic acid added as preservative.

Prepared by the Smith-Dorsey Company, Lincoln, Neb. No U. S. patent or trademark.

Emulsion Liquid Petrolatum with 5 grains Phenolphthalein per fluid ounce, Chocolate Flavored: A palatable emulsion containing 60 per cent (by volume) of liquid petrolatum, 0.32 Gm. (5 grains) of phenolphthalein-U. S. P., 1 per cent agar agar per fluidounce and 0.1 per cent of benzoic acid added as preservative.

Prepared by the Smith-Dorsey Company, Lincoln, Neb. No U. S. patent or trademark.

THIAMIN CHLORIDE (See New and Nonofficial Remedies, 1939, p. 498).

The following dosage form has been accepted:

Thiamin Chloride Tablets-Stearns, 1.0 mg.: Each tablet represents 100 U. S. P. units of thiamin chloride.

Prepared by Frederick Stearns & Co., Detroit, Mich.

CONCENTRATED POLLEN EXTRACT-ABBOTT (See New and Nonofficial Remedies, 1939, p. 37).

The following dosage form has been accepted:

Mixed Grass Concentrated Pollen Extract-Abbott (Blue Grass, Timothy, Orchard Grass, Red Top, and Sweet Vernal Grass in equal parts).

Prepared by Abbott Laboratories, North Chicago, Ill.

MANDELIC ACID (See New and Nonofficial Remedies, 1939, p. 313).

Mandelic Acid-Merck.—A brand of mandelic acid-N. S. R.

Manufactured by Merck & Co., Inc., New York. No U. S. patent or trademark.

INDUSTRIAL HEALTH

A GENERAL STATEMENT OF MEDICAL RELATIONSHIPS IN INDUSTRY PRESENTED BY THE COUNCIL ON INDUSTRIAL HEALTH

The Council on Industrial Health was created in 1937 as a standing committee of the Board of Trustees of the American Medical Association to assist the physician individually and through the agencies of medical organization to enlarge and improve his contribution to the health of the industrial worker. In recognition of the essentially educational nature of its functions the Council has accumulated information derived from a variety of sources which, together with investigations undertaken on its own account, are submitted in this special issue of *THE JOURNAL*. The complexity of relationships not only in industry itself but among the many organizations which are attempting to solve the health problems of the worker makes it impossible to include in this introductory discussion all the aspects of industrial health in which physicians, in one way or another, are interested. The Council acknowledges the assistance which it has received from physicians and other sources in the preparation of this subject matter.

It would be difficult to discover any field in the basic or clinical medical sciences which has not contributed to or been affected by health problems in industry. Nevertheless external influences, mostly socio-economic in nature, have played a considerable part in directing this interest into effective channels. These factors, mostly growing out of the increasing complexity of industrial and technologic development, have expressed themselves in a long train of social legislation. One phase of this legislation which has affected the medical profession particularly stems from the concept that injuries and diseases arising out of or occurring in the course of employment are chargeable to industry as part of the cost of production. This attitude has been implemented by the enactment of workmen's compensation statutes. Once adopted, compensation laws have forced on industry and the medical profession the realization that the majority of industrial accidents and unhealthful exposures are in the main preventable. Likewise it has become apparent that improved health of the worker through medical supervision and engineering control of industrial environment, as a rule, favorably affects rates of industrial production.

The period over which workmen's compensation laws have exerted an influence on medical practice in the United States covers about thirty years. The entire development of purposful health control over workers, therefore, falls well within the professional experience of many physicians in practice today. The early reliance on curative and reconstructive measures lumped under the general heading of compensation practice is no longer sufficient. Only through the principles of preventive medicine can the physical and environmental status of working people be successfully improved. The range of interest, therefore, has grown immeasurably under the double impulsion of humanitarian and economic influences not alone in clinical fields but in improved organization, administration and investigation. The principal manifestations of this expanding

program currently are the incorporation of occupational diseases into workmen's compensation coverage and the growing conviction that many of the problems of adult hygiene have occupational implications that can be most successfully combated by using the industrial approach.

THE SCOPE OF INDUSTRIAL HEALTH

Industrial health is an inclusive term, incorporating three major types of activity.

1. Medical and surgical care to accomplish prompt restoration to health and earning capacity following industrial accident or disease.
2. Prevention of disease or injury in industry by the establishment of proper control over industrial environment.
3. Education of employees about healthful living, both in and out of the industrial environment.

Industrial health, then, in the broad use of the term, is a composite of current knowledge drawn from medicine, surgery, nursing, sanitation and health education.

Fifteenth Census of the United States: 1930, Occupation Statistics.

A real understanding of industrial health must be based on a recognition of the part which each of these components plays and the relationships which practicing physicians have established or should establish with them.

POPULATION GROUPS INVOLVED

Another expression of the scope and importance which industrial health has come to occupy rests principally on the great numbers of the population involved. The first table illustrates the divisions and subdivisions of the gainfully employed by sex and by major occupational classification. These figures, while they are inapplicable today because of considerable shifts in employment, still provide some insight into the relative distribution of wage earners according to occupation. Fifty million people represent 39.8 per cent of the total population and nearly 50 per cent of the population 10 years old and over. Any program which has as its principal objectives the improvement of the health of such a large segment of the population must necessarily be of paramount importance to the medical profession.

THE UNEVEN DISTRIBUTION OF INDUSTRIAL HEALTH SERVICES

The dangerous trades are largely concentrated in the manufacturing, mechanical and mining industries, which provide employment to about fifteen million wage earners. These groups, as a result, have received the greatest amount of attention from industrial physicians and

TABLE 2.—*Industrial Establishments Classified According to Number of Wage Earners in the United States*

Establishments Employing	Number of Establishments	Number of Wage Earners
No wage earners.....	6,885	
1 to 5 wage earners.....	62,164	170,174

hygienists. Of the hundreds of listed occupations which are considered potentially hazardous to health, a major portion will be found in these occupational classifications. Attention needs to be directed to other classes of wage earners in order to identify and control such unhealthful exposures as may exist. Of equal importance is the uneven application of industrial hygiene as between large and small manufacturing plants. Plants

and satisfactory both to those who supply the service and to those who receive it, a substantial level of medical achievement will have been reached.

EFFECTS OF OCCUPATION ON HEALTH

The clearest evidence of direct relationship between occupation and life expectancy lies in the excessive accident and disease rates which attach to certain employments. For example, loggers, structural ironworkers, riggers and explosive makers are subjected to such unusual risks as to make them either ineligible for life insurance protection or acceptable only at much higher premium rates. Workers in dusty trades feel themselves in a similar position, as do those exposed to industrial poisoning or to the hazardous effects of other industrial environments either by direct effect or through increased incidence of tuberculosis, pneumonia, cancer and possibly other degenerative diseases. Many statistical approaches have been undertaken to appraise the general effects of occupation on mortality, including the study of labor union records, reports of workmen's compensation agencies and insurance companies, and death certificates. None have proved entirely satisfactory. The absence of uniform and usable statistics is a serious obstacle to a rational attack on those occupational factors which most closely affect the public welfare. Statisticians have attempted to throw some light on the subject by grouping data referring to specific occupations into broader socio-economic classifications. The most recent study in this country along these lines has been prepared by Whitney, drawn from mortality data in the 1930 United States Census and published by the National Tuberculosis Association (table 3).

TABLE 3.—*Standardized Death Rates from Specified Causes per 100,000 Gainfully Occupied Males 15 to 64 Years of Age According to Occupational Classes, 1930*

Occupational Classes	Death Rates per 100,000 Occupied Males

Standardized according to age distribution of all gainfully occupied males in ten selected states: Alabama, Connecticut, Illinois, Kansas, Massachusetts, Minnesota, New Jersey, New York, Ohio and Wisconsin.

employing 1,000 or more workers have, on the whole, found themselves in the most advantageous position to organize and maintain reasonably complete medical services. Table 2 demonstrates the overwhelming number of manufacturing establishments which fall below this rank. Roughly, one half of the workers in manufacturing plants are employed in establishments having fewer than 250 persons. Of all manufacturing concerns, 97 per cent are found in this category.

Extending industrial medical service to small plants is a difficult problem. When means are found to provide qualified medical assistance in the control of industrial hazards universally, approximating the character of service now supplied in many large industrial units

Most difficulty is experienced in dissociating the direct effects of daily work on life expectancy from the coincident effects of domestic environment, hereditary influences, general intelligence and other social and economic factors, of which income, housing and nutrition are conspicuous examples. Very likely, many occupations carry no particular health risk at all or the occupational factor in mortality is so small as scarcely to be measurable. Certain employments appear to have positive health advantages, as, for example, agriculture and the professions (table 3). In any event, considerable improvement has occurred in the life expectancy of wage earners during recent years. At least in some disease classifications improvement has proceeded with

greater momentum than in the general population. Contributors to these results have been the safety movement, the improved application of industrial hygiene, the establishment of industrial medical services and the interest which workmen themselves are assuming in health matters.

Mortality statistics do not represent the actual health status of any group, and wage earners are no exception. Yet morbidity data referring to occupations are, on the whole, even more unsatisfactory than death records. Excellent analyses are available with respect to the effect on health of certain specific occupational exposures and the incidence of permanent and temporary disability resulting from industrial accidents. Various studies also have been made on the general incidence of sickness of all types causing absenteeism. The ability to evaluate properly the etiologic relationships of occupation to unhealthy states and to record them promptly and in sufficient detail will constitute one of the major contributions of the medical profession to the industrial health movement.

INDUSTRIAL ACCIDENTS

Injury or death caused by industrial accidents constitutes, for a good share of the medical profession, the only appreciable contact they have had with industrial problems. Accidents rank second among males and fourth in the total population as a cause of death (table 4). Occupational fatalities among white male policyholders of the Metropolitan Life Insurance Company accounted for 20.4 deaths per hundred thousand in 1938. In 1913 the rate reached as high as 45.7. Industrial injury rates follow more or less closely the curves of employment and business activity, but the 50 per cent decline in deaths from industrial injury is, at least in part, the result of concentrated efforts by industry to control the causes and consequences of accidents. Table 5, derived from the Bureau of Labor Statistics, U. S. Department of Labor, is a compilation of the estimated number of disabling injuries occurring in 1938 by industry groups. Certain of these figures are stated to be derived from incomplete and fragmentary sources.

Industrial accidents, as usually defined, are injuries arising out of and in the course of employment. Accident statistics are compiled in terms of frequency and

further classifications are possible—into fatal and non-fatal cases, the latter susceptible of reclassification according to whether the effects of injury are permanent or temporary.

The industrial accident problem has been regarded so long as an economic, industrial and engineering problem

TABLE 5.—Estimated Number of Disabling Injuries During 1938, by Industry Groups

severity. Frequency rates are an expression of the number of accidents per million man hours of work exposure. Much effort has been expended in developing uniform methods of reporting, but data from various sources must be examined critically because of variations in scope, definition of accident, and the method of accident exposure calculation. Severity rates are compiled on the basis of the extent of the resulting incapacity expressed in days of lost time per thousand man hours of work. From the point of view of severity,

that its medical aspects have been to a considerable degree overlooked. The associated factors can be understood best through examining two major aspects—prevention and individual medical management. Prevention deserves first consideration and, in most instances, has received it. Such tactics appeal to industrialists as businesslike, since reduced accidents result in reduced compensation insurance premiums. Out of this interest have grown the safety movement and the professional approaches represented by safety and industrial hygiene engineers. As developed in this country, the major functions of prevention of industrial accidents have grouped themselves into subdivisions representing research, engineering, safety education and medical control.

Research includes the study of reports and the analysis of all available statistics regarding the causes and consequences of accidents. Sources of information are industrial commissions, state departments of labor and insurance companies, all of which compile valuable analyses of accident experience and causation. The Bureau of Labor Statistics of the U. S. Department of Labor and the National Safety Council are the most important agencies gathering and correlating raw industrial accident data.

The engineering aspect of accident prevention refers to the control of mechanical factors, either those which cause accidents or those introduced to reduce hazards. Through such methods sound safety practices are established and safety codes formulated which ultimately constitute a basis for safety legislation.

Education relates to general propaganda as well as individual and group instruction in the avoidance of accidents. Safety contests, meetings, posters and similar functions are important parts of such programs.

Medical industrial accident control consists of physical examination of workers, both prior to employment and periodically during the course of employment. When properly conducted, such examinations promote safe placement of applicants for work and maintain regular employees in positions geared to mental and physical capacity. Minor physical defects are not necessarily significant in industrial physical supervision and should not carry too much weight in the total evaluation of the individual. Gross physical defects should be given the importance they deserve. Much emphasis is currently attached to the study of the worker from the point of view of accident proneness. These investigations involve appraisal of the psychomotor apparatus and personality types in order that placement may occur in work consistent with least risk and greatest aptitude. The rapid growth in the use of automatic machinery is a case in point, altering the role of the worker from that of a machine operator to that of a machine tender. Changes of this character may bring about severe alterations in the attitude of the worker to his job. A much higher degree of selection among personality types is therefore involved in order to prevent monotony, fatigue and dissatisfaction. Furthermore, laxness in concentration on the industrial operation is a prolific cause of accidents and is directly related to such social and economic conditions as income, housing and nutrition. All together, there are a wide variety of factors which are considered to have greater or lesser effect on accident occurrence which need to be understood by physicians, such as age, length of time on the job, time of day, character of ventilation, illumination, and other considerations which may be personal to the worker or affecting groups of workers.

The second important aspect of the industrial accident problem refers to competent medical care of the injured worker. This implies suitable medical organization for control of accidents and immediate treatment. Control and treatment are accomplished through first aid, nursing, part or full time physicians and arrangements for hospitalization. The value of treatment will be determined by the qualifications of the physician not solely from a surgical point of view but according to his intimate knowledge of the total industrial problem. An ideal result for all concerned would be full restoration of the injured workman to his former earning capacity in the same line of work and with minimum loss of time. Approximations to this standard will constitute the measure of successful medical management, which must be sympathetic and tactful enough to instill a desire to get well and return to work. The medical and legal responsibilities relating to the determination of temporary and permanent disability and the completion and prompt filing of forms and blanks for industrial commissions and insurance companies must be accepted as an obligation as well as a field for some necessary reform.

OCCUPATIONAL DISEASES

Occupational diseases, troublesome as they are to certain industries, are for industry as a whole the least important cause of lost time disability (table 6). Reliable statistics about the incidence of occupational diseases are scarce and, to complicate the picture still more, not much is known about the chronic or subacute effects of long continued exposure to low concentrations of toxic industrial materials. Even to define occupational diseases has proved difficult, as the language used in the

TABLE 6.—*Absenteeism from Illness and Injury in Industry*

statute relating to occupational disease in Illinois described elsewhere in this issue amply illustrates.

To facilitate understanding, attempts have been made to classify occupational diseases. Bulletin 582 of the Bureau of Labor Statistics, U. S. Department of Labor, contains such a classification prepared by Dublin and Vane under the following headings:

- A. Abnormalities of temperature and humidity.
 1. Extreme dry heat.
 2. Heat and humidity.
 3. Sudden variations of temperature.
- B. Compressed air.
- C. Dampness.
- D. Defective illumination.
- E. Dust.
 1. Inorganic dust.
 2. Organic dust.
- F. Infections.
 1. Anthrax.
 2. Hookworm.
 3. Septic infections.
- G. Radiant energy.
 1. X-rays, radium and other radioactive substances.
 2. Ultraviolet and infra-red rays.
- H. Repeated motion, pressure, shock.
- J. Poisons.

These headings provide some insight into the general nature and causes of occupational diseases, all of which will be subjects for more extensive treatment in subsequent publications by the Council.

Occupational disease reporting needs particular emphasis. No disease can be controlled unless its nature and extent can be ascertained with reasonable accuracy. Some states, therefore, have attempted to secure such information by making occupational diseases reportable by physicians. The value of such reports is obvious, but results have been negligible because physicians frequently fail to recognize occupation as an etiologic factor in disease. The limited notations about occupation on death certificates constitute the only evidence possessed by many state health departments regarding the occurrence and effects on health of industrial exposures.

A number of states have enacted workmen's compensation laws covering occupational diseases. Some have schedules specifying the occupational diseases which come within the scope of the statutes. Certain

jurisdictions compensate for occupational diseases under all inclusive acts often referred to as blanket coverage. Included in these classifications are the principal industrial states in this country. Since adequate information based on the reporting of occupational diseases by physicians is largely nonexistent, an index to their prevalence has been sought in the number of these diseases which have been compensated, especially in the predominantly industrial states. Accurate as the reports of compensation boards are in other respects, data on occupational disease are fragmentary and difficult to assess. Diseases listed in a schedule adopted by a state and actual diseases reported by the industrial commission as compensated may bear no close relationship. Even when statistics are carefully kept, the use of inclusive terms makes detailed information difficult to secure. Silicosis and asbestosis may be included under the term "tuberculosis—all forms" and acute industrial poisoning may be lumped under the heading "poisonous and corrosive substances." Present evidence, however, indicates that occupational disease claims of all types are increasing in number and in cost. Industrial dermatitis is far and away the most prevalent cause, approaching 70 per cent of closed claims in some areas. Good conclusions about other aspects of occupational disease must await the adoption of standardized reporting according to terminology which renders them identifiable in all states, no matter what methods are employed for extending compensation coverage.

ORDINARY ILLNESS IN INDUSTRY

Industrial accidents and occupational diseases have received most attention from industrial physicians and hygienists. They are associated with work as proximate cause, a relationship which has been recognized in workmen's compensation practice. It has been, therefore, to the advantage of industrialists first to seek out means for reducing the frequency and severity of work related disability. Yet in industry accidents and occupational diseases account for a very small proportion of all time lost by workers to disabling injury or sickness. Data shown in table 6, derived from studies conducted by the American College of Surgeons, illustrate the much greater probability of lost time from ordinary illness than from accident or disease arising out of work. These and other data indicate that male workers lose nearly nine days annually to disabling sickness or injury, and in every thousand male workers every year nearly one hundred absences of seven days or longer will occur. As a rule there will be more sickness among women employees, both as to frequency and extent, and more among married than single women. The principal causes of lost time in industry for men and women both are the diseases and complaints which make up the bulk of general practice everywhere. This is, in the main, true regarding absences of longer or shorter duration. Economically, losses in wages and through disruptions in production schedules must be estimated in billions of dollars each year.

Although not responsible for ordinary sickness and injury, there are excellent incentives for industry to analyze uniformly and regularly all lost time by employees, no matter what the cause, duration or end result. Such information is the best available guide to the need for specific health activity in industry and the directions it should take. The merits of this type of approach have been amply demonstrated to industry by the published analyses of morbidity and mortality data

by public health and other agencies. Uniform methods of recording work absence will assist greatly toward clarifying relationships between physical and mental capacity or defect as revealed by physical supervision and lost time. Only fragmentary data are available which correlate these factors with occupation, skill and experience as well as age, sex, color, marital status, duration of illness and other factors needed for straight or comparative statistical purposes. Likewise, the beneficial aspects of controlled and accurately recorded observations about the health of employed groups obviously cannot be restricted to industry or the industrial employee alone. They can hardly fail of providing much better understanding of community health problems as a whole.

When causes of lost time are considered, a good share of the medical problems of industrial health fall clearly in the province of private medical practice. The extension of preventive medical methods in order to reduce all loss of time, absenteeism and short work spans is one of the objectives of industrial health. Results will be accomplished best if public health workers in industry and in the government recognize the contributions which private physicians in general and special practice can and ought to make towards more adequate health control over workers in both large and small industry. The interests of the worker are best served if the interdependence of all elements in the profession is accepted as a proper foundation for the development of a well balanced industrial health program.

THE PHYSICIAN IN INDUSTRY

The simplest way to classify physicians practicing in industry is in relation to the time they devote to it—full time, part time or on call. Much confusion has occurred in professional minds from a failure clearly to distinguish the objectives of these groups. In a strict sense the full time industrial physician represents in the whole field of medicine that segment of special interest which applies the theory and practice of medicine to the health of employed groups. As such the work they do is set apart from the individual case work of the private practitioner whose contribution to industrial health mainly restricts itself to curative and reconstructive phases of occupational injuries and diseases. Even under this limited type of service it is estimated that private physicians engaged in general or specialty prac-

tice supply more than four fifths of the medical service which industry is obliged to give or which it provides in an enlightened view of the effects of unhealthy exposure on employees and hence on production.

The record of growing interest in industrial medical services and the increasing recognition of the usefulness of such a career are shown in the accompanying table drawn from the American Medical Directory. These tabulations demonstrate substantial increases during the last few years in the number of physicians limiting or giving special attention to industrial practice.

According to Selby, industrial medicine as practiced by competent and ethical physicians who devote all or

a major share of their activities to it attempts to furnish employees with the best possible health protection consistent with:

1. The purpose of industry.
2. The employer's responsibility as fixed by law for competent care and prevention of occupational injury and disease.
3. The employee's right to free choice of medical counsel in all health matters not occupational in origin.

The relationships which ordinarily need most clarification as between physicians in industry and private practitioners refer to three principal lines of activity—industrial hygiene, physical supervision and therapy.

INDUSTRIAL HYGIENE

It has been quite generally felt that the physician in industry fulfils his function best if he regards himself, over and above statutory requirements, as health officer of the plant responsible for plant hygiene. His special

* In the plant or readily available.

understanding of the control of industrial exposures constitutes the professional equipment which distinguishes his activity from ordinary private practice and from conventional preventive medicine as well. He advises and assists employers to protect workmen against physical impairment arising out of occupational environment. His success is measured according to his familiarity with toxic agents and harmful processes, the adequacy of protective devices and their suitable maintenance, and particularly the persistence with which he pursues practical solutions of these problems. Activities such as these are in the best tradition of preventive medicine and do not involve competitive relationships with private practice. Nevertheless, the medical profession has certain very definite opportunities and responsibilities toward furthering and upholding standards of industrial hygiene.

Employers of all grades will become more generally aware of the importance of industrial hygiene as values are demonstrated through practical application by fellow employers, through the impetus provided by the workmen's compensation statutes and through the urgings of the industrial organizations and trade asso-

ciations themselves. Once an employer develops an interest in controlling plant hygiene problems, he is likely to turn first to the physician who takes care of his industrial injuries. If this source fails him, as it frequently does, helpful assistance may be obtained only with great difficulty. Every physician has on this basis then an opportunity for constructive preventive medical achievement which no amount of personal distaste ought to impel him to ignore. It is the function of medical organization and education to prepare private physicians either to give reliable advice directly about industrial health service or to acquaint him with sources of authoritative information.

PHYSICAL SUPERVISION

Effective as industrial hygiene has proved to be, other useful practices have come to be included as functions of industrial medical service. Alleged aggravation, by the nature of the work, of preexisting and coexisting diseases not in themselves occupational in origin has necessitated physical examination of applicants for work. Properly, these are conducted at the time of employment to assure safe placement and often enough thereafter to assure protection against diseases originating in or unfavorably influenced by occupation, and for diagnosis to establish the occupational or nonoccupational origin of disability.

In respect to physical supervision, two major considerations present themselves as factors affecting relationships of private physicians to industry. In increasing numbers of plants they are likely to be called on to undertake physical examinations of workers which, aside from certain medicolegal considerations, they ought to be competent to perform provided they supply the service with as much impartiality as it is possible to assume. The usefulness of this service will be greatly increased if physicians have good knowledge of the working conditions, materials and processes to which examinees are exposed.

Of far greater importance to private physicians are the enormous number of physical defects which are uncovered by industrial physical examinations. Correction of these defects is a function not of industry but of private practice. Efforts which the physician in industry, full or part time, can undertake in bringing together family physicians and the workers needing medical care have such beneficial aspects to all concerned as hardly to warrant argument. Deviations from this principle on the part of physicians in industry who have used industrial connections as an unfair competitive device in the development of private practice constitute the major reasons why industrial medicine has suffered severely in the eyes of the general medical profession.

THERAPY

Workmen's compensation acts have obliged employers to furnish treatment. In a great many instances medical services in industry grew out of this obligation. As a rule there is little disposition by employers to assume any responsibility for treatment beyond this point. The variable elements of friction which have existed between the industrial physician and the private practitioner in respect to freedom of choice of medical counsel for the care of not only ordinary sickness but industrial disability are much more likely to diminish than otherwise. The full time industrial physician, if present trends prevail, will be less and less a therapist and more and more an administrator of public health

through the application of industrial hygiene. In that capacity he should assume a public health function and act as a case finder for the private physician and specialist, through whom the direct remedial service should be applied. He should act as an active participant in the rehabilitation of injured workers through selection of suitable occupational therapy in the sense of restoration to earning capacity under conditions of controlled work. With these exceptions and the attention to minor injuries or ailments for which the worker consults the plant physician largely because he is accessible and no lost time is involved, therapy is likely to be a diminishing segment of the industrial medical officer's activity. This trend of industrial medicine to ally itself with private practice in the care of industrial patients needs to be widely extended. Much will depend

8. Impartial health appraisals of all workers.
9. Provision of rehabilitation services within industry.
10. The conduct of a beneficial health education program.

An attempt has been made by the Council on Industrial Health to determine the frequency with which these services are provided by industrial physicians in plants of varying sizes and types. Requests were first addressed to secretaries of state and county medical societies for as complete lists as possible of all physicians engaged full or part time in industrial practice. By this means a total of 2,544 names was secured. To every other one of these names, arranged alphabetically according to states, a questionnaire was directed. No two physicians were employed in the same plant. Four hundred and twenty-five tabulatable replies were

COMPARISON OF MEDICAL SERVICES SUPPLIED BY PLANTS OF VARYING SIZES.

on the private physician's capacity to care for compensable disability competently and with the least possible loss of working time. Incompetent, dilatory or dishonest practices in this field are not only thoroughly unprofessional but are, in the industrial field, private practice's most active competitor.

FUNCTIONS OF MEDICAL SERVICE IN INDUSTRY

The functions of medical service in industry, then, can be listed as:

1. Regular appraisal of plant sanitation.
2. Periodic inspection for occupational disease hazards.
3. Adoption and maintenance of adequate control measures.
4. Provision of first aid and emergency services.
5. Prompt and early treatment for all illnesses resulting from occupational exposure.
6. Reference to the family physician of individuals with conditions needing attention, cooperating with the patient and his physician in every practical way to remedy the condition.
7. Uniform recording of absenteeism due to all types of disability.

received containing data supplied by the physicians responsible for health control in 611 individual establishments and for 1,120,062 employees.

Table 8 classifies services supplied by industrial physicians according to size of plant and demonstrates in adjoining columns the ability of plants of varying capacity to support the principal components of industrial medical services. The distribution of industrial plants according to size in the sample is shown in the table. Of the 1,120,062 employees covered, nearly 90 per cent were found to be in the largest units. All plants had at least part time medical service. Full time physicians were reported in 47 per cent of the plants employing more than 1,000 workers and in none of those employing fewer than 100. The data regarding full time nursing service show a similar diminution from the large to the small plants, almost fading out entirely in the establishments employing under 100 men. In this group 92 per cent of the plants had no nursing services at all.

First aid services and the care of compensation cases are quite uniformly supplied in plants of all sizes because of legal requirements existing in most of the states. In all other respects the smaller the plant the greater does it appear at a disadvantage in the supplying of industrial medical service. The more complete provision of preventive medical service in large plants is reflected in such activities as preemployment and periodic examinations, accident and disease prevention, plant sanitation, health education and medical advisory services. The latter refers particularly to advice supplied about physical defects not occupational in origin and testifies in a great many cases to cooperative relationships which are developing between industrial medical services and the workers' family physicians. In plants of all sizes physical examination of applicants for work is observed to a much higher degree than subsequent periodic surveys. X-ray and clinical laboratories are said to be located in the plants or "readily

* In the plant or readily available.

available," in a substantial proportion of establishments in all classifications, a reflection of the need for precise information about the physical condition of applicants and, less regularly, for other employees, unless they are exposed to harmful materials and processes. The extent to which consulting radiologists and clinical pathologists are used is not known, but presumably in ordinary cases their services will not be called for. The question of standardized technic and the competence of interpretation of radiologic and pathologic examinations in industry needs additional investigation. The provision of physical therapy equipment in these plants is appreciable in all categories, presumably to facilitate follow-up care of industrial injuries where this type of restorative treatment can be applied with the smallest amount of lost time. Diagnostic dental service, on the other hand, is largely underdeveloped in industry, although correctable dental defects are the most frequent conditions found in industrial physical examinations. Other consulting services most frequently mentioned are those supplied by ophthalmologists and dermatologists.

The nature of the industry in which these medical services are organized is shown in table 9. The pre-

dominance of manufacturing and mechanical industries in the tabulation is a natural one indicative of the predominance of harmful industrial exposures in occupations falling in this group. Mines are well represented in all the medical service brackets and, to a somewhat less extent, transportation and communication. Most of the examples of extended medical service mentioned in the replies to the questionnaire were reported from these groups. In most of the other categories, figures are too small to have much significance.

Industrial health services according to this evidence have proved to be most advantageously developed in large plants. In all classifications according to size, however, there are any number of opportunities for useful medical activity in a relatively unexplored field. Many of the small plants which have comparatively unsatisfactory accident and occupational disease experience will look to the medical profession for guidance and assistance. Such demands ought to be anticipated through education applied to physicians everywhere. There is a definite place for the physician in every industrial plant, large or small. Until industry and labor are taught to recognize that place and to realize the value of intelligent health conservation, the full potentialities of industrial health as a contributor to community and national welfare will not be realized.

INDUSTRIAL HEALTH ACTIVITIES IN ORGANIZED MEDICINE

All of the official agencies in organized medicine have exerted direct or indirect influences on the standards and procedures of industrial medical practice. One of the useful functions of the Council on Industrial Health will be to coordinate these activities as well as to point out to physicians the functions of extraprofessional groups and associations which take an interest in the health of the worker.

The growing interest in industrial health is demonstrated by the increased space assigned in THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION directly to items indexed under the titles of industrial medicine and workmen's compensation, jumping from thirty-eight references in 1920 to 164 in 1938. This subject matter refers to original articles, editorials, queries and minor notes and abstracts and has no reference to the large amount of additional information in THE JOURNAL directly applicable to improved industrial medical standards. Other agencies in organized medicine have made valuable contributions to professional understanding of social and medical values in industrial health. Workmen's compensation legislation has periodically been surveyed, beginning with the investigation by the Judicial Council in 1915 and since by that agency as well as by the Bureau of Medical Economics. Since its creation, the Bureau of Legal Medicine and Legislation has kept closely in touch with the developments in the field of workmen's compensation legislation. It has advised state associations with respect to such legislation, urging, among other things, that injured employees be given the right to choose the physician who treat their injuries, and has exerted its influence to the end that only scientific medical care be made available to injured workmen. The Bureau has also followed the trend of judicial decisions relating to workmen's compensation and abstracts the more important decisions for publication in the medicolegal columns of THE JOURNAL. A Committee on Industrial Sanitation was appointed in 1915 by the Section on Preventive

Medicine and Public Health, which reported in the following year that the great mass of workmen had been denied the opportunity of enjoying healthful living and working and predicted a large field of opportunity open to the physician in the industrial field. The scope of activity which physicians could profitably engage in was outlined by this committee and includes substantially all the functions now considered applicable to present day industrial medicine. Discussions of industrial medical problems have been so continuously presented in that section since that industrial medicine shortly came to be included in its title. The Bureau of Health Education has furthered the cause of physical examination in industry through the development of health examination forms and a physical examination manual. The Council on Physical Therapy has engaged in investigations of resuscitation equipment, artificial limbs and estimations of disability from hearing loss, following to some degree the fundamental work of the Section on Ophthalmology relating to disability from visual loss. Other councils and bureaus have exerted a less direct but important influence in industrial medical standards. The ethical code takes on real significance when applied to medical service for industrial wage earners. The condemnation of quackery and cultism benefits industry as well as the general population. Industrial medicine benefits by every improvement in undergraduate teaching, postgraduate medical instruction, adequate standards of hospital training, licensure and specialist certification. All these activities represent contributions by organized medicine to improve medical care for the whole population and visualize, therefore, in no small degree, that the industrial worker will be one of the principal beneficiaries.

Activities in State and County Medical Associations.
—Early in the development of the Council on Industrial Health a policy was adopted regarding its relationship to state and county medical societies in the following terms:

Contact should be made with the several state medical societies, urging them to create committees on industrial health which will proceed at once to study the problems in this field in their respective communities. The organization of committees should be extended as far as practicable to the county medical societies. These committees should be urged to investigate the present activities within their states of the several agencies interested in industrial health, as well as the proposals for industrial legislation which are being presented to various legislatures. Educational programs should also be sponsored under the auspices of these committees.

Early investigation showed that, while a fair percentage of the states had formed committees dealing with certain aspects of industrial health, centralization of responsibility was largely absent and functions, were in many instances distributed through several committees, such as public policy and legislation, economics, contract practice and workmen's compensation, all of whom might act independently on economic, ethical or clinical matters relating to industrial health.

The evident need for coordination of activities under a definite program has appealed to a majority of the state medical associations. At the present time thirty-four of the state medical associations have formed committees on industrial health or indicated existing committees through which the Council can act in its efforts to clarify the objectives of industrial health and to elevate its standards. The committees and chairman of each are listed in table 10.

A program of activities for these committees has been formulated with the following objectives:

1. Train physicians to recognize and report occupational disease.
2. Train industry and labor to the value of industrial health conservation.
3. Elevate medical relations and standards under workmen's compensation.
4. Scrutinize all social legislation affecting industrial health.
5. Clarify relationships between industrial and private practitioners.
6. Improve relations between physicians and insurance.
7. Establish working relationships with all state agencies interested in industrial health.

Feeling that some effective means of interchange of ideas between the Council and the state committees other than correspondence would enhance organization, provide uniformity of action and stimulate wider initiative, a bulletin has been developed through which it is hoped objectives will be more rapidly realized.

Already certain county medical societies are beginning to organize committees of their own to provide for proper medical leadership in respect to health measures designed for employed groups. These developments are of first importance, since it is in the county medical society that problems of industrial health are encountered earliest and where they are most directly dealt with. The functions of investigation, correlation and education which characterize the programs of the Council on Industrial Health and of the committees on

industrial health in the state medical associations are susceptible of extension into county units. Although no fixed formula can be established for county society activities because of the wide variety of local conditions, it is felt that the three classifications of activity that have been mentioned are flexible enough for general need and yet provide a basis for reasonable uniformity and consistency.

INDUSTRIAL HEALTH IN THE GOVERNMENT

As in the case of private medical practice, the scope and administrative procedures in workmen's compensation have determined the extent and characteristics of activities by governmental agencies directed at industrial health problems. Under forms of compensation benefits restricted to industrial accidents only, principal reliance came to be placed on state departments of labor or industrial commissions who created factory inspection

Industrial hygiene activity in state governments has been greatly expanded recently by assistance available under the Social Security Act of 1935. Under the guidance of the United States Public Health Service this work has developed in three principal directions:

1. Administrative functions concerned with coordinating all activity undertaken by federal, state and unofficial agencies.
2. The extension of industrial hygiene units in state and local health departments.
3. Studies and investigations carried on by the laboratory and field sections of the Division of Industrial Hygiene.

All these activities are carried out cooperatively with health departments, with industry, with physicians and with other organizations. The accompanying table lists the industrial hygiene bureaus now incorporated in state governments. Two are assigned to state departments of labor in New York and Massachusetts. In addition

(1) Personnel now being established.

tion services and issued regulations under factory acts designed to suppress unsafe practices and working conditions. As workmen's compensation widens and extends coverage to occupational diseases, the desirability for establishing more adequate forms of governmental control has begun to exert itself.

Exceptions to this general statement in the federal government are the United States Bureau of Mines and the United States Public Health Service, which separately and jointly have engaged in valuable industrial health activity for more than a quarter of a century. The United States Public Health Service, through its Division of Industrial Hygiene in the National Institute of Health, has contributed greatly to administrative standards of industrial hygiene through its program of research, education and cooperative services. The Division of Labor Standards in the United States Department of Labor was established in 1934. It is designed to formulate codes of safe procedure under model laws which the individual states may adopt. One of its most valuable contributions has been the establishment of regional training schools for factory inspectors.

to those listed, bureaus have been developed in a number of city and county health departments. Essentially, however, the functions of bureaus of industrial hygiene are identical and include:

1. Consultation with plant management regarding needed corrections of environmental conditions.
2. Advice to the management and medical supervisor as to the relative toxicity of materials or processes, and advice concerning new materials prior to their introduction into the industry.
3. Assistance in developing, maintaining and analyzing absenteeism records.
4. Consultant service to medical supervisors, private physicians, compensation authorities and other state agencies regarding illness affecting workers.
5. Provision of necessary laboratory service of both a clinical and a physical nature.
6. Integration of the activities of other public health bureaus in their programs for workers; for example, the control of cancer, syphilis and tuberculosis.

Determinations of the scope and nature of industrial health problems in any locality are necessary to indicate

the kind, magnitude and direction of work to be undertaken. Most of the industrial hygiene units in state health departments are now in the process of conducting or have recently completed preliminary industrial hygiene surveys. Fundamental information of this character provides a basis for extensive education of industrial officials and physicians in order to secure reliable reports on absenteeism due to occupational disease and other illnesses. Representatives from divisions of industrial hygiene in the state and federal governments constitute the National Conference of Governmental Industrial Hygienists, the objectives of which are to promote industrial hygiene and sanitation in all its aspects and to coordinate these activities as conducted by governmental units. Annual meetings are conducted to accomplish these purposes.

INDUSTRIAL MEDICAL EDUCATION

The training which physicians receive in industrial health could be greatly improved. This fact has made it necessary to investigate the availability of educational facilities in industrial health and to determine the possibilities for expansion. The tabulations and discussion which follow represent an attempt by the Council on Industrial Health to determine whether the medical profession has been hampered in its relationship to a useful and growing segment of medical enterprise through negligent emphasis on undergraduate and post-graduate teaching programs.

Few practitioners in present day industrial medicine have had opportunity for formal education. Varying degrees of proficiency have been attained through personal experience or apprenticeship. Such traditional methods are successful in medical education until information has been assembled, special technics elaborated and precise knowledge accumulated sufficient to establish a special field of medical interest. When that point is reached, experience demonstrates that organization of instruction leads to more efficient preparation. Time is saved, the spread of authentic information is greater, the interests of patients are more adequately safeguarded and, in general, the gap between knowledge and practice is materially reduced.

Industrial health as practiced today is not a restricted field. In this respect it resembles all other special provinces of medical interest. Physicians engaged in industrial practice in a limited way believe that any one with good basic medical equipment can successfully conduct an industrial practice with certain adaptations which are to be gained largely through experience. A contrary point of view is expressed by those engaged in industrial practice full time, who state that industrial health requires a degree of preparation on the part of those who elect to serve therein quite as exacting as to be found in any other specialty. Furthermore, they contend that successful industrial medical specialization demands additional proficiency mainly in the field of administrative practice.

Obviously, the educational requirements for these two groups are dissimilar; but, if growing demands on the profession are satisfactorily to be met, most practitioners will need some training in industrial health to establish competence and some practitioners will need a great deal, in keeping with the varying situations and circumstances under which industrial practice occurs.

PRESENT STATUS OF UNDERGRADUATE TEACHING

The importance of acquainting medical students with the fundamentals of industrial hygiene is rarely questioned by those in charge of teaching preventive medicine in medical schools. There are always difficulties associated with substantial alterations of or additions to teaching schedules. Table 12, representing data collected by the Council on Industrial Health, indicates

† Information received for the academic year 1938-1939.

that adequate presentation of industrial hygiene to undergraduates is by no means impossible. Given proper leadership and organization, industrial hygiene can occupy a position of real significance in the time devoted to preventive medical teaching. Industrial hygiene is a function of preventive medicine in most of the medical schools. This relationship is of considerable interest, since such backwardness as industrial hygiene has displayed in attracting the attention of medical educators is a reflection of the difficulties encountered in the teaching of preventive medicine and

public health methods as a whole. As improvement occurs in this larger field, the impression prevails that industrial hygiene will come in for its own share of augmented representation.

Reports have been received on the present status of undergraduate teaching in industrial hygiene from all of the approved four year medical colleges. Fifty-two medical schools shown in table 12 are able to report quantitatively the time assigned to required instruction in industrial hygiene. Six schools are unable to report in this fashion because of the difficulty of applying a numerical value to the industrial hygiene content of conjoint courses, seminars and related preventive medical teaching. Nine schools in which no organized instruction in the subject is given are also omitted from the table. The average allotment of time devoted to industrial hygiene in the listed schools is slightly in excess of five hours. Actually, of the fifty-two schools providing some instruction, twenty exceed this average figure and thirty-two fall below it, the variability

extending from one hour of didactic work to as much as twenty-two hours of lectures, associated clinics and demonstrations.

Required laboratory exercises especially in industrial pathology or physiology are omitted from the tabulation, since experience of this type is provided in only four of the medical schools. Field trips which must be considered in the same ratio of importance to industrial hygiene teaching as bedside demonstrations are to clinical medicine and surgery are required in twenty-seven schools. The most effective procedure has usually taken the form of visits to industrial medical services. Another arrangement is to include an investigation of industrial hygiene as part of a required general sanitary survey by each student. In either case the satisfactory nature of the experience is predicated on the degree of supervision exercised, the character of follow-up reports and the presence or absence of associated seminars. In certain schools this phase of the teaching is admirably done. Elsewhere the value of current practices has been seriously questioned.

Table 13 lists the twelve medical schools which offer optional courses in industrial hygiene, all offered by departments of public health and preventive medicine. In several schools, electives are available in other components of industrial health provided by departments of general medicine, surgery, toxicology and ortho-

pedics. In a few others, clinical experience of a combined medical-surgical type is made available through industrial outpatient dispensaries. As noted in the case of required instruction, considerable variation exists in the elective courses, ranging from thirty hours of didactic work, field trips and laboratory exercises to elective field trips alone. The degree of student interest also may vary considerably. Elective courses have developed on the basis of student demand. Others have been offered for a number of years with practically no registrants.

CORRELATING EXPERIENCE IN OTHER TEACHING DEPARTMENTS

In many of the medical schools the claim is properly made that lack of emphasis on industrial hygiene in separately conducted preventive medical courses should not be the sole standard by which the adequacy of teaching industrial health as a whole is measured. The basis of this argument rests on the fact that industrial health is a composite of contributions from nearly every other teaching discipline in medical education and its complete presentation is possible only through appropriate experience supplied by departments of surgery, medicine, dermatology, radiology, toxicology and medical jurisprudence. In fact, it has been suggested that the application of preventive methods should not be segregated in separate courses but should form an integral part of the instruction which medical students receive in all clinical courses. Valid as these contentions are, evidence is accumulating that adequate coverage of industrial health is an unusual accomplishment under systems of divided and unrelated responsibility; unless the task of suitable correlation is lodged in one or another of the component teaching units. It is thought that correlation of this character could effectively be undertaken by those in charge of preventive medicine and public health departments, since the educational content of these courses likewise supplies a substantial increment to industrial health training. The essentials of personal and physiologic hygiene, nutrition and housing, vital statistics, general sanitation and control of communicable diseases are all directly applicable. Certainly organization of instruction along these lines should correct to some extent the charges that medical problems surrounding the health of the workers are not adequately presented and that instruction in common occupational health exposures is available only as typical cases happen to be admitted to wards or clinics. It should serve also to reduce the number of complaints relating to inadequacy of training in the care of traumatic injuries, in occupational dermatitis and in industrial toxicology and jurisprudence.

Separate departments of industrial hygiene have been created at the University of Pittsburgh School of Medicine and at the University of Colorado Medical School in the expectation that this type of organization presumably will provide a different but successful solution to teaching industrial health more adequately. Important as such developments may be in undergraduate teaching, greater significance resides in the specialized teaching talent which can be attracted under such a plan, particularly if graduate programs are under consideration.

As the advantages of this type of organization become apparent, other medical schools may follow suit. In fact, such plans have already been contemplated at a number of teaching centers.

CONTACT OF THE PROFESSION WITH
INDUSTRIAL HEALTH

Lack of emphasis on occupational problems is accounted for in some medical schools on the assumption that proficiency in industrial practice should be a function of graduate medical education as in the case of any other medical or surgical specialty. This point of view fails to consider the early contact which recent graduates establish with practical industrial medicine, similar in every respect to problems they encounter falling within the scope of other specialties the fundamentals of which are taught in clinical courses. Recent graduates of approved medical schools listed in the American Medical Directory as engaged in general practice have reported to the Council on Industrial Health that nearly 60 per cent are introduced to industrial medicine and surgery very promptly in their professional careers. Almost none of them have had any opportunity to undertake postgraduate training beyond such fortuitous experience as they may have received as house officers in hospitals. Table 15 presents information received from this group of recent medical graduates calculated to determine their appraisal of the adequacy of training in certain components of industrial health. The replies, while they have small value in reference to the adequacy of training received in individual schools, do provide an index to the competence of the average recent graduate to undertake industrial practice. The majority feel that, while first aid surgery and principles of resuscitation are adequately taught, they are not quite so sure about the commoner industrial health hazards. With respect to industrial toxicology, industrial dermatosis, standards of ventilation and illumination, principles of workmen's compensation and casualty insurance relationships, the majority of recent graduates feel that these subjects are inadequately treated and in that descending order. These replies are a direct commentary on the reliability of contributions to industrial health experience provided by unrelated clinical departments without necessary planning and organization. They also refute the attitude that instruction of medical students in industrial health is not practical and that such teaching has no direct bearing on competence in the general practice of medicine.

AVAILABILITY OF TEACHING TALENT AND
CLINICAL MATERIAL

Another explanation provided by certain of the medical schools for inability to develop suitable teaching programs in industrial health refers to the lack of available teaching talent and clinical material. This is particularly true of schools located in nonindustrial areas. Information sought and obtained from a substantial list of physicians in charge of industrial medical departments questions this point of view with respect to most sections of the country. The majority of replies from this source express the belief that recent graduates as a rule are not well prepared to contribute promptly and properly to medical control of working people. The principal criticisms of recent recruits to industrial medicine, aside from almost complete absence of any previous contact with industrial problems, fall in four main classifications:

1. Inability to adjust to the medical control of groups.
2. Poor insight into preventive practice of all types.
3. Almost no conception of disability evaluation.
4. Little conception of the contribution which physicians can make to personnel relationships in industry.

In the opinion of these industrial medical directors, most of the difficulties can be laid at the doors of medical schools as they have failed to use industrial facilities to extend the knowledge of medical students along industrial lines. The majority express the feeling that these facilities are readily available in nearly every locality and ought to be freely used.

POSTGRADUATE EDUCATION IN INDUSTRIAL
HEALTH

Much more fault ordinarily is found with the lack of adequate graduate opportunities in industrial health than deficiencies in the undergraduate curriculum. In consideration of the degree of industrialization involved, little interest has been exhibited in this country toward the development of centers of advanced training in industrial practice. The meager record may be reported under the following headings:

University Programs.—Existing opportunities for advanced instruction have developed in the same way noted in the discussion of undergraduate teaching as part of the larger field of preventive medicine. Since most of these opportunities are designed for candidates interested in higher public health degrees, there has been little disposition to distinguish between such educational

TABLE 14.—Schools Providing Advanced Industrial Hygiene

requirements and those needed to turn out a well trained plant medical director. The necessary basic information may be identical in all cases but the practical superstructure might be somewhat different. In any event, physicians may be deterred from undertaking further training in industrial health if the only means for so doing involve registration for all courses leading to certification or a degree in public health.

Table 14 lists those schools which report industrial hygiene as a component of advanced courses in public health and preventive medicine. Two of them are in schools of public health; the remainder are associated with advanced public health training either in medical or in graduate schools. A great deal of variation exists in the amount of time devoted to industrial hygiene and the availability of suitable clinical material just as in the case of the undergraduate schools. In certain of these schools it is possible to plan an individual program for the capable graduate student adjusted more or less to his needs and interests both as to time and as to content.

The number of short continuation courses under university auspices is likewise strictly limited. Efforts along these lines have been successful at Buffalo, Northwestern, Wayne, the New York Postgraduate School and Pittsburgh universities, the latter in conjunction with the county medical society.

Nevertheless there are some encouraging prospects for a substantial growth in university controlled gradu-

ate courses in industrial health in the near future. Most of these plans depend on the augmentation of teaching programs in public health departments. In one or two instances, plans are being undertaken to organize institutes of industrial health open to a variety of candidates including graduate medical students. The opportunities available under such an arrangement would appear to come closer to meeting the needs of the practitioner interested in a plant medical service than has yet been attained.

Special Professional Societies and Organizations.—The special professional societies in the field of industrial medicine and surgery have made very effective contributions toward the dissemination of reliable information in the field of industrial medicine and surgery. Benefits derived by the membership do not extend to private practitioners who provide the greater part of medical service in industry, except as they have access to official publications and proceedings. Such organizations as the American Association of Industrial Physicians and Surgeons and its component societies, the industrial sections of the American Medical Association

and the American Public Health Association, the National Safety Council, the clinical conferences of the American College of Surgeons, railway surgical societies and members of district, state and local bodies fall into this category.

In addition, independent organizations have over a period of years arranged for special seminars on industrial health topics. Typical examples are the Saranac Symposiums on Silicosis and the meetings of the Air Hygiene Foundation. The United States Public Health Service has also supplied training for the benefit of personnel in industrial hygiene units of state boards of health.

State and County Medical Societies.—The survey of postgraduate medical education conducted by the Council on Medical Education and Hospitals of the American Medical Association indicates that industrial health has received almost no consideration as a topic for presentation. Traumatic surgery is the only component which has aroused any considerable interest. In a series of answers submitted by 479 industrial physicians, 165 report that their county medical societies devote time to discussions of industrial health. Nevertheless it is safe to say that on the whole there has been little organized effort to acquaint the practicing profession with best methods to improve the physical and environmental status of workers.

Considerable improvement is looked for in this respect. The Council on Industrial Health has inaugurated an annual congress on industrial health which will serve to acquaint the practicing profession with current developments in this field. These congresses will be supplemented by postgraduate educational programs in the state societies under the stimulus of the committees on industrial health in the constituent organizations. It is expected also that as these plans materialize there will be greater attention to industrial medical affairs in county medical society meetings and committee deliberations. In this way a fuller realization of the importance of industrial health will be provided the organized medical profession or at least there will be an opportunity to arrive at accurate conclusions as to why there is lack of interest and the best means of combating it.

Internships, Residencies and Fellowships.—The degree to which hospital experience augments acquaintance with industrial medicine is reported in table 15. One hundred and five, or 67 per cent, of recent graduates reached by questionnaire have stated that their knowledge of occupational health problems was improved by hospital training. These additions to industrial health knowledge probably occurred with few concerted attempts on the part of staff intern committees to organize the instruction. The opportunities available through hospital training have not received the attention which they deserve and the Council on Industrial Health will be interested in determining whether the available industrial clinical material in hospitals is diversified enough to be effectively used in these directions.

Hospital experience may also contribute to the training of industrial physicians by the residency method. There are only a handful of approved residencies bearing on industrial health, all falling in the field of traumatic surgery. If hospitals can supply contact with suitable clinical material both bed and ambulatory, and if such training can be combined with additional periods of laboratory experience for basic instruction in industrial pathology and physiology and with a period of controlled service in a well conducted plant medical department, the resulting product should be a very acceptable one to industry. Such a plan would have the effect of formalizing and organizing educational opportunities for graduates interested in industrial medical practice in a fashion which has served effectively in all other specialty programs and relieve the universities of the full burden of providing acceptable advanced instruction.

But few fellowships are reported except as they relate to specific problems of investigation in one or the other of the components of industrial health as, for example, air conditioning, fever therapy and chemical exposures. Social security fellowships have been available designed to enhance the qualifications of the present personnel in divisions of industrial hygiene in state boards of health. Appointments of this type deserve great extension if any considerable reservoir of teaching and investigative ability is to be developed. They offer an exceptional approach to a sound understanding of industrial health from the graduate teaching point of view provided the character of support and the necessity for original investigation do not narrow concepts so appreciably as to make adequate experience negligible outside the field of primary interest.

MEDICINE IN INDUSTRY

Industry deals with men as well as with machinery and materials. Only recently, however, has industry begun to realize that the man who operates the machine and who fabricates the material is its most valuable asset. As this conviction grows, fostered by both manufacturing and trade associations, employers are beginning to look more and more to the medical profession for assistance in conserving the physical welfare of man power. Already medicine has, under a variety of circumstances and in all types of industry, so convincingly demonstrated its value in reducing lost time from preventable accidents and diseases that it has come to be considered quite as indispensable as any other of industry's maintenance functions.

Probably it will never be easy to bring to industry generally the advantages of medical and engineering control over unhealthful industrial exposures. Aside from those ordinary activities of medical service in industry usually included under emergency surgery, industrial hygiene and physical supervision, the essential functions of industrial medicine demand study of technologic changes and the introduction of new materials, and the development of methods of control. These difficult procedures require integration and coordination, functions which constitute for the profession at large the principal objectives of the Council on Industrial Health.

Of equal complexity is the problem of unequal distribution of medical service to industry. Large plants, on the whole, have found themselves in the best position to organize medical services. Yet, contrary to common impression, industry in this country is made up predominantly of small units. Ninety-seven per cent of all manufacturing concerns employ fewer than 250 men, and almost 70,000 of them employ five wage earners or fewer. In this segment of industry, accident and disease experience is thought to be less favorable on the whole than in large plants. In this same segment the principal medical service received is first aid and

emergency surgery and care of compensable disability. From the point of view of preventive industrial medical service, the field of the small plant is almost unexplored. When it is found possible to extend qualified preventive medical assistance to such concerns, through the joint agencies of private practice and public health administration satisfactory to those who supply the service and to those who receive it, an achievement will have been recorded in which all elements in the medical profession can take lasting satisfaction.

CHRONIC INDUSTRIAL BENZENE
POISONING

An important and valuable addition to our understanding of the nature of chronic benzene poisoning in industrial workers is furnished by a series of five papers¹ which recently appeared in the *Journal of Industrial Hygiene*. They come from the Labor Departments of Massachusetts and New York, and from the Massachusetts General Hospital and the Hospital of the Rockefeller Institute for Medical Research. To any physician who has flattered himself that he has a clear and well founded picture of this form of industrial intoxication, these papers will bring an unpleasant shock, for they cast doubt on many of the ideas that have been held in the past with regard to pathology, diagnosis, clinical course and susceptibility. Indeed, they leave the impression that here is a disease of decided variability, one which requires the most meticulous examination if a diagnosis is to be made in time to save life. Moreover, the failure to make an early diagnosis sometimes means death to the victim.

The picture of chronic benzene poisoning as generally conceived includes a typical aplastic leukopenia, with or without a marked anemia, thrombocytopenia, increased bleeding time, delayed clotting and complete absence of any regenerative forms, white or red, in the circulating blood. Necropsy reveals a hypoplastic marrow. No other form of blood disease can be attributed to the action of benzene. Women, especially young girls, are more susceptible than men and suffer more severely. Early benzene poisoning can be readily detected by a count, absolute and relative, of the white

1. The papers have been issued in monograph form and can be obtained from 55 Shattuck Street, Boston, price \$1:

blood cells or by Yant's test for urine sulfates. A concentration of not over 100 parts per million of benzene in the air may be considered a safe limit.

All these assertions are challenged, more or less positively, by these writers. To take the last first, Bowditch and Elkins state that the concentration should be kept down to 75 parts per million at the most but that even at this point susceptible human beings may develop severe, even fatal, poisoning, which means that there must be close medical, as well as factory, control. Hunter says "It is doubtful whether any concentration of benzene greater than zero is safe over a long period of time."

The classic picture of benzene aplastic anemia is found to be only one of the manifestations of this disease. Hunter, who reports the result of the blood examinations in eighty-nine cases and the clinical course in ten fatal and four nonfatal cases, states that chronic benzene intoxication may bring about polycythemia or anemia, leukoerythemia or leukopenia, leukemia or leukemoid blood pictures (either lymphatic or myeloid), eosinophilia, megaloerythemia or microcytosis, or the presence of immature marrow elements in otherwise normal blood. Mallory and his colleagues made fourteen necropsies and five biopsies on people exposed to benzene. They

find that the picture in the bone marrow varies from severe hypoplasia to the most extreme form of hyperplasia with extramedullary hematopoiesis, hyperplasia being more common than hypoplasia. The hyperplastic activity in marrow and in other foci may in some cases be hard to distinguish from tumors. The most surprising feature in these two reports is the statement that two of the fatal cases showed not leukopenia but leukemia, one a case of acute myeloid leukemia and the other acute aleukemic leukemia. The necropsy results in both cases confirmed the clinical diagnosis. In the first case a nodule was found in the liver which proved to be a true leukemic tumor, displacing the liver cells. Mallory emphasizes the "neoplastic tendency" of the conditions in all the cases belonging to the hyperplastic types. Among the nine cases observed by Erf and Rhoads, treatment failed in only one, in which an acute myeloid leukemia developed, with death six months after. Here too the appearance at necropsy

was characteristic. There are, therefore, three new cases of benzene leukemia added to the ten already reported in the literature.

The diagnosis of benzene poisoning in an early stage is not easy. Hunter's case histories show that the victim may reach an advanced stage before there are striking blood changes or clinical symptoms. Leukopenia is not the most frequent sign. Both Hunter's group and Greenburg's group find a fall in the red cell count, below 4.5 million, more trustworthy. In the twenty-nine cases examined in Boston, anemia was always present but leukopenia was absent in ten. Yet one of these was fatal. In the New York cases also leukopenia was absent in some of the early cases and also in some of the cases of severe involvement.

Next in importance to the anemia the New York group places an increase in the size of the erythrocytes. These observers also note that thrombocytopenia may be present without prolonged bleeding and delayed clot retraction. The Boston group lays stress on a decrease in the polymorphonuclear percentage, which is a better index of early poisoning than either leukopenia or an absolute polymorphonuclear decrease.

Yant's test for decrease in the proportion of inorganic to organic sulfates in the urine was used by Bowditch and Elkins,

who found a striking difference between forenoon and afternoon specimens. The normal ratio fell as the day went on, to rise again slowly during the course of the evening. They found it a valuable test for benzene absorption.

Hunter says that he did not find any evidence that women are more seriously injured by benzene than men. Mallory says that among his sixteen cases of severe poisoning there were twelve men and four women. Ten of the men showed marrow hyperplasia and only two aplasia, while all four women showed aplasia, which suggests that there is a tendency of the male to react with hyperplasia, which may help to explain, since the hyperplastic form has not yet been generally recognized, the prevailing belief that women are more susceptible than men. His two patients with leukemia were men, and Erf and Rhoads' patient was a man. Of the ten cases reported in the literature, eight were in men.

THE PLATFORM OF THE AMERICAN MEDICAL ASSOCIATION

The American Medical Association advocates:

1. The establishment of an agency of the federal government under which shall be coordinated and administered all medical and health functions of the federal government exclusive of those of the Army and Navy.
2. The allotment of such funds as the Congress may make available to any state in actual need, for the prevention of disease, the promotion of health and the care of the sick on proof of such need.
3. The principle that the care of the public health and the provision of medical service to the sick is primarily a local responsibility.
4. The development of a mechanism for meeting the needs of expansion of preventive medical services with local determination of needs and local control of administration.
5. The extension of medical care for the indigent and the medically indigent with local determination of needs and local control of administration.
6. In the extension of medical services to all the people, the utmost utilization of qualified medical and hospital facilities already established.
7. The continued development of the private practice of medicine, subject to such changes as may be necessary to maintain the quality of medical services and to increase their availability.
8. Expansion of public health and medical services consistent with the American system of democracy.

Current Comment

THE SECOND ANNUAL CONGRESS ON INDUSTRIAL HEALTH

The Council on Industrial Health recently concluded the second of its annual congresses on industrial health. The meeting was attended by nearly three hundred leaders in industrial health, including representation from private and industrial practice, officers and members of committees on industrial health in state and county medical societies, directors of industrial hygiene and workmen's compensation in federal and state governments, insurance company officials, industrial and public health nurses, and lay executives and personnel officers of manufacturing enterprises interested in recent developments in the industrial health field. The character of attendance and the interest expressed testified to the need for a meeting of this character designed to clarify from time to time the scope, methods and objectives of all phases of medical practice in industry. Several suggestions were made by participants in the programs which seemed to warrant further exploration. One recommendation referred to the desirability of discussions leading toward closer collaboration in the physical and vocational rehabilitation of the industrially injured among representatives of organized medicine, workmen's compensation administration and rehabilitation agencies. The individual injured worker might profit considerably if all agencies designed to restore him to earning capacity worked together rather than at cross purposes, as all too frequently occurs under present uncoordinated conditions. Another suggestion was to the effect that the Council on Industrial Health should enlist the aid of appropriate sections in the Scientific Assembly of the American Medical Association to develop whenever possible uniform points of view about the relation of trauma to disease and also to inquire into the possibility of standardizing disability evaluation. The work of the Section on Ophthalmology in relation to disability rating for visual loss was cited as an example of what can be accomplished under proper interest and leadership.

THE RANDOLPH CASE

Newspapers in Philadelphia recently waxed well-nigh hysterical again about the case of an infant who died, it is said, not only because of failure to get a physician but because the physician ultimately reached failed to respond to the call. Now a calm, dispassionate investigation is reported in the *Weekly Roster*, bulletin of the county medical society. The baby, named Randolph, was 1 month old. The mother was delivered without a physician but with the assistance of a neighbor woman. The parents, who had four other children, had been on relief for the past five years. The mother observed at 8 a. m. that her baby was ill. At 8 p. m., according to the newspaper account, she sent to a neighbor's house for the father, who sent his two older children to get a physician. Walking through the cold after dusk on Sunday, these youngsters passed the homes of several doctors but, seeing no lights, passed by. They did not ring the door bells or knock. When

the children returned two hours later, the mother had her daughter telephone the doctor who had been called when her delivery had already been facilitated by a neighbor. This doctor lived three miles away and had emergency work which would keep him busy for an hour. He urged the Randolphs to try the neighborhood physicians again. The mother now "walked" the baby until it went asleep. When she awoke at 12:40 a. m., the baby was white. She sent the husband for the police, who took the baby to the hospital, where it was pronounced dead. Apparently the mother had assumed that the physician who had attended her would drop all other cases regardless of their seriousness and come at once. She made no further effort to get a physician near her home. Actually he was busily engaged with two other emergency cases that might also have proved fatal. This fact the Philadelphia newspapers ignored. Philadelphia has 4,221 physicians, eighty-eight hospitals, more than 384,000 telephones and several directories of physicians; also a large number of adult persons who could run errands. Had the quest for a doctor been intelligently conducted by neighbors or other adults, a physician would have been obtained.

AMINO ACIDS OF CANCEROUS TISSUE

The search for chemical distinctions between normal and cancerous tissues has been diligently prosecuted in an effort to gain an insight into the factors involved in causing the rapid, unregulated growth of malignant tissue. The suggestion that several amino acids in malignant tissues occur as the unnatural stereo-isomers has been cited¹ as the first definite evidence of a qualitative difference in the metabolism of normal and malignant tissues. Now the accuracy of this initial evidence is questioned. Indeed, a recent investigation² has, by virtue of the specificity of the methods employed and the critical and controlled experiments conducted, quite conclusively demonstrated that the reported existence of large proportions of the unnatural stereo-isomer of glutamic acid or of other amino acids in malignant tissues cannot be correct. Employing a d-amino acid oxidase enzyme preparation which specifically deaminizes only the unnatural stereo-isomers of amino acids, a collaborative research by investigators of Cornell University and of the National Cancer Institute has studied the action of this enzyme preparation on hydrolysates obtained from purified protein preparations, from normal tissues and from a wide variety of malignant tissues. Although a small proportion (less than 3 per cent) of the unnatural stereo-isomers is found in all hydrolysates studied, significant differences were not observed in the relative concentrations of the unnatural forms of the amino acids in malignant tissues as contrasted with normal tissues or to purified proteins. Certainly the great importance initially attached to the type of spatial configuration of certain of the amino acids of cancerous tissue would appear to be unwarranted as far as the problem of the etiology or diagnosis of cancer is concerned.

ORGANIZATION SECTION

THE COMMITTEE OF PHYSICIANS FOR THE IMPROVEMENT OF MEDICAL CARE, INC.

REPORT SUBMITTED AT THE REQUEST OF THE EDITOR OF THE JOURNAL

The Committee of Physicians for the Improvement of Medical Care has been in existence about two and one-half years. Its origin, early history and purposes were described in articles which appeared in the *New England Journal of Medicine* (217: 843 [Nov. 18], 884, 887 [Nov. 25] 1937). A short article was also published in *THE JOURNAL* (March 12, 1938, p. 141B). Since then the committee has continued its activities in accordance with the principles and proposals which constituted its original platform.

The general objectives of the committee are set forth in the following quotation from its first statement:

They [the members of the committee] hope that these principles and proposals may suggest the lines along which effort may be made by voluntary, local, state and federal agencies to improve medical care. It is recognized that the medical profession is only one of several groups to which medical care is of vital concern. . . . Nevertheless the medical profession should initiate any proposed changes because physicians are the experts upon whom communities must depend.

The purposes of the committee are further indicated by the following quotations from a statement issued May 5, 1939:

The Committee has embarked on the second part of its work, the critical analysis of general or national movements toward the reorganization of medical care. . . . It is their [its members'] intention to subject to scrutiny and to expose to the light of public opinion, and more especially to the physicians of this country, projects or actions of government or of organized medical or lay groups. . . . They regard their functions as interpretative and educative. They appreciate the presence of all shades of opinion among those to whom they are responsible and have, consequently, tried to avoid arbitrary assertions. They have felt constrained to adopt an uncompromising attitude toward projects or measures that obviously violate the fundamental ends for which they have united, namely the protection and improvement of the quality of medical care. But they are equally solicitous that no systems be imposed of such uniform and stereotyped patterns that experiment and evolutionary development will be deterred. In fact they have proclaimed interest in education and investigation, establishment, maintenance and improvement of standards of competence and merit, the need for expert control, all features that are incompatible with static uniformity.

In this spirit the committee has issued, at intervals, the following statements: Aug. 8, 1938, Report of the National Health Conference; Nov. 26, 1938, Analysis of the National Health Conference and the program presented by the Interdepartmental Committee at that conference, with comments on the action of the House of Delegates of the American Medical Association (Sept. 16, 1938); May 5, 1939, The Wagner Bill (S. 1620) and Its Implications; Aug. 15, 1939, Proposals for Amendment of the Wagner Bill and an abstract of Senate Subcommittee Report (No. 1139) on Establishing a National Health Program.

The committee has repeatedly asserted the adherence of its members to the American Medical Association but has insisted that they and all individuals and groups have not only the right but the obligation to discuss freely any subject affecting medical practice, even if their opinions conflict with the policies and actions of those governing any medical organization.

The committee is now composed of thirty-one physicians. There are approximately 1,000 signatories to the Principles and Proposals and about 150 additional names are on the mailing list. Signature of the Principles and Proposals is not a prerequisite for being placed on the mailing list. The committee remains a self-appointed group. It has been incorporated as a non-profit corporation under the laws of Connecticut for the usual reasons of legal formality. The idea of more formal national organization with local chapters and democratic representation was considered and referred to the signatories but was not acted on for several reasons: the wish to avoid organization propaganda, the uneven distribution of the signatories, the cost involved, and the belief that such organization would give rise to the impression that the committee is working in opposition to and outside the ranks of the American Medical Association. Signatories have been invited to take the initiative, as individuals or as groups, in nominating persons for membership on the committee and suggesting or criticizing activities of the committee.

The work of the committee has been supported thus far by voluntary contributions from members of the committee and the signatories. Its expenses for the year July 1, 1938-1939, amounted altogether to about \$2,500. The committee will be glad to mail to physicians who are interested copies of its statements, or to add their names to its mailing list.

Present members of the committee include:

Dr. Richard M. Smith, chairman	Dr. Channing Frothingham
Dr. Hugh Cabot, vice chairman	Dr. H. Rawle Geyelin
Dr. William J. Kerr, vice chairman	Dr. F. T. H'Doubler
Dr. Russell L. Cecil, honorary chairman	Dr. L. Emmett Holt Jr.
Dr. John P. Peters, secretary	Dr. William S. Ladd
Dr. J. Rosslyn Earp	Dr. H. Clifford Loos
Dr. Robert B. Osgood	Dr. Harry S. Mackler
Dr. S. Borden Veeder	Dr. William S. McCann
Dr. Milton C. Winternitz	Dr. T. Grier Miller
Dr. Philip King Brown	Dr. George R. Minot
Dr. Allan M. Butler	Dr. Hugh Morgan
Dr. Louis Casamajor	Dr. LeRoy S. Peters
Dr. Thomas B. Cooley	Dr. G. Canby Robinson
	Dr. David Seegal
	Dr. John H. Stokes
	Dr. James J. Waring
	Dr. Mortimer Warren
	Dr. Soma Weiss

New Haven, Conn.

GRADUATE MEDICAL EDUCATION

A PROGRESS REPORT OF THE FIELD STUDY ON GRADUATE MEDICAL EDUCATION IN THE UNITED STATES
BEING CONDUCTED BY THE COUNCIL ON MEDICAL EDUCATION AND HOSPITALS

SOUTH CAROLINA

The South Carolina Medical Association has appreciated the necessity for some form of graduate education for the physicians of the state. It has been difficult for many of the physicians practicing in South Carolina to visit the leading medical centers elsewhere for a sufficient period for graduate study. For this reason a workable statewide program of extension training has been needed. Several plans have been tried and, while all have been of some service, not until recently has any one plan seemed to fit the need of the state.

In 1938 a cooperative program was developed between the Medical College of the State of South Carolina and the state board of health. A statewide course in obstetrics was given by the professor of obstetrics in the medical college. Twenty counties were visited from June to September 1938. Six meetings were held in each locality over a six weeks period. Two hours was devoted to illustrated lectures and clinics. Meetings were held in local hospitals whenever possible. Subjects included were treatment of abortions, placenta praevia and separation of the placenta, adequate antepartum care, toxemias of pregnancy, normal labor, operative procedures in obstetrics and puerperal care. Attendance totaled 196 physicians, health officers and nurses. There are 980 members of the South

Carolina Medical Association of the 1,354 licensed in the state. No registration fee was charged for this instruction, since federal funds were utilized.

The Piedmont Postgraduate Clinical Assembly began in 1934 with clinical lectures by Dr. J. R. McCord, who visited six sections of the state under the auspices of the Children's Bureau of the United States Department of Labor. A permanent local organization followed, which had a broader scope. General medicine and surgery have been considered and a new aspect of medicine is stressed each year. Faculty members from medical schools of the South with South Carolina physicians conduct the three day program, which is designed to meet the needs of physicians practicing in South Carolina and neighboring states. A registration fee of \$2 is charged. Attendance has averaged 100 physicians.

The office of the state medical association developed a library in 1938 so that members of the association might have library facilities in the state. Approximately 100 periodicals and 1,000 reference books in medicine are available.

Three sanatoriums in the state have offered conferences in tuberculosis for physicians. At Pinelhaven Sanatorium, such conferences have been given annually. It is believed that fifty Negro physicians have taken some instruction in tuberculosis during the past few years.

MEDICAL LEGISLATION

MEDICAL BILLS IN CONGRESS

Bills Introduced.—S. 3266, introduced by Senator Hill, of Alabama, provides for pensions, compensation, retirement pay and hospital benefits to reserve officers of the Air Corps of the Army who were called or ordered into the active military service with the Air Corps, Regular Army, by the federal government for extended military service in excess of thirty days on or subsequent to July 1, 1928, and who suffered disability in line of duty. S. 3269, introduced by Senator Mead, of New York, proposes to authorize a federal appropriation of \$300,000,000 from which loans may be made to public bodies and nonprofit organizations for hospital, water, sewer, stream pollution control, and related projects and facilities. The bill provides that not exceeding \$100,000,000 may be devoted to hospital projects. S. 3279, introduced by Senator Pepper, of Florida, proposes to increase from \$3,500,000 to \$4,500,000 the appropriation for vocational rehabilitation in order that needy disabled persons may receive aid in acquiring artificial appliances. S. 3318, introduced by Senator Sheppard, of Texas, proposes to authorize the appointment of female dietitians and female physical therapy aides in the Medical Department of the Army. H. R. 8289, introduced by Representative Wallgren, of Washington, proposes to authorize not to exceed \$2,500,000 to enable the Secretary of the Interior to construct, equip and operate a hospital for the legally adjudged insane of Alaska. H. R. 8332, introduced by Representative Sumners, of Texas, proposes to prohibit the transportation of obscene literature in interstate or foreign commerce.

STATE MEDICAL LEGISLATION

Mississippi

Bills Passed.—The following bills have passed the house: H. 118 proposing to authorize the Board of Supervisors of Washington County to convey certain land to the city of Leland, on which the city of Leland is to erect a public health center and clinic; and H. 126 proposing to empower the board of supervisors of any county to acquire the necessary real estate and to expend any amount deemed necessary for the erection and maintenance of community public health centers and clinics used in connection with the syphilis eradication program sponsored by public health units of any county.

Bills Introduced.—SCR 6 proposes to create a committee to ascertain and compile full data and information pertaining to the state's charity hospital facilities. H. 174 proposes to authorize the boards of supervisors of the various counties to levy and collect an ad valorem tax not to exceed 2 mills for the treatment of the indigent sick, for the promotion of public health and for the support and maintenance of a full time county health department.

New Jersey

Bills Introduced.—S. 46 proposes to enact a separate chiropractic practice act and to create an independent board of chiropractic examiners to examine and license applicants for licenses to practice chiropractic. A license to practice chiropractic, the bill provides, confers on the licensee the right to diagnose and to regulate the patient's dietary, sanitary and hygienic habits; to use the title "Doctor" or "Dr." when accompanied by "Chiropractic" or "Philosopher of Chiropractic" or "Master of Chiropractic," or their abbreviations, and to employ nurses; but it does not give the licensee the right to practice medicine, surgery, obstetrics or osteopathy. A. 155 proposes to enact a separate naturopathic practice act and to create an independent board of naturopathic examiners to examine and license applicants for licenses to practice naturopathy, which the bill defines as "that system of the healing art which uses and prescribes the following practices and usages: diagnosis and the practice of the combined physiological, mechanical and material sciences of healing as taught in schools, institutes and colleges of naturopathy, which shall include physiotherapy, hydrotherapy, mechanotherapy, psychotherapy, phytotherapy, electrotherapeutics, corrective and orthopedic gymnastics, external applications, manipulation, and nutritional control." S. 64 proposes that 25 per cent of the receipts from motor vehicle licenses, from auto drivers' licenses and from gasoline tax receipts shall be set aside as a voluntary nonprofit general hospital fund, which is to be disbursed to voluntary nonprofit general hospitals in the state in proportion to the number of beds each such hospital has available for the use of indigent patients injured in automobile accidents.

New York

Bills Introduced.—A. 981 proposes to enact a separate chiropractic practice act and to create an independent board of chiropractic examiners to examine and license persons applying for

Virginia

Bill Passed.—H. 7 has passed the house, proposing to prohibit the issuance of a license to marry unless both parties to a proposed marriage present a physician's certificate, which is not to disclose any medical finding, that he has conducted such tests and examinations as are required to determine whether there is evidence of syphilis. The bill proposes to require a physician to inform a person whom he has examined for the purpose of executing such certificate and in whom he has found indications as to the presence of syphilis, and the other party to the proposed marriage, the result of the test he has performed, the nature of the disease and the possibilities of transmitting it to the marital partner and to their children.

Bill Introduced.—H. 120 proposes to enact a separate chiropractic practice act and to create an independent board of examiners to examine and license applicants for licenses to practice chiropractic. The bill defines chiropractic "as the philosophy, science and art of locating, any method preparatory to, and the adjustment of the articulation of the spinal column and adjacent bony structure to release the transmission of nerve energy to all parts of the body to correct the cause of disease." The bill proposes to authorize a chiropractor "to use such methods as taught by chiropractic schools and colleges to further assist in establishing the normal transmission of nerve energy." Chiropractic, the bill continues, is not to include the use of operative surgery, obstetrics, osteopathy, nor the administration or prescribing of any drug or medicine. A certificate to practice chiropractic is to confer on the licensee the right to practice as may be incident to such practice, and to use the title "Doctor" or "Dr." in connection with his name when accompanied by the word "Chiropractor" or the letters D.C."

Bill Introduced.—H. 658 proposes a system of compulsory health insurance, the benefits of which are to consist of cash and all forms of medical, dental, nursing and hospital service to be supplied to persons embraced in the compulsory features of the bill and to such others as elect to come under the bill.

Rhode Island

Bill Introduced.—H. 658 proposes a system of compulsory health insurance, the benefits of which are to consist of cash and all forms of medical, dental, nursing and hospital service to be supplied to persons embraced in the compulsory features of the bill and to such others as elect to come under the bill.

OFFICIAL NOTES

SPECIAL BLUE NETWORK BROADCAST

On February 21 from 9 to 9:30 p. m. central standard time (10 to 10:30 eastern standard time, 8 to 8:30 mountain time and 7 to 7:30 Pacific time) there will be a special broadcast by the American Medical Association and the National Broadcasting Company over seventy stations of the Blue network. The subject will be "Pasteur Conquers Rabies." The broadcast will be based on an article entitled "Watch Your Dog!" appearing simultaneously in *Hygeia* and on official reports dealing with the seriousness of the rabies situation in the United States. Special features of the program will be music arranged by Don Markotte of the National Broadcasting Company Music Library from the score which accompanied the motion picture based on the life of Louis Pasteur, starring Paul Muni. This music is made available through the special courtesy of Warner Brothers. An augmented N. B. C. orchestra, directed by Joseph Gallicchio, will render the music. Dramatizations taken from the life of Pasteur and arranged for radio by William J. Murphy will be enacted by a specially selected cast of N. B. C. radio actors, under the direction of J. Clinton Stanley, director of the series *Medicine in the News*.

A limited number of tickets for admission to the studio will be available to physicians in Chicago and vicinity. Tickets will be limited to two per application. Requests should be sent by mail to the Bureau of Health Education, American Medical Association, 535 North Dearborn Street, Chicago, enclosing a stamped, self-addressed envelop. Telephone requests cannot be received. Applications will be filled in the order in which they are received until all the tickets have been distributed.

WOMAN'S AUXILIARY

Louisiana
The auxiliary to the Calcasieu Parish Medical Society met in Lake Charles, October 20. Mr. R. F. Cisco spoke on the "Functioning of the By-Laws of the Association of Commerce." Arrangements were made for donations for Thanksgiving and Christmas food baskets for needy families. Also members were to assist the doctors in establishing the new library in St. Patrick's Hospital. Prizes will be given to children in the parish schools who write the best essays on a subject selected from *Hygeia*. At the November meeting Dr. Walter Moss gave an illustrated lecture on "Cancer Control." Dr. Claybrook Cottingham, president of Louisiana College, spoke on "World Events." Mrs. S. M. Blakeshear, president of the auxiliary to the Louisiana State Medical Society, spoke on "Organization and Cooperation" at a meeting of the auxiliary to the Rapides Parish Medical Society, Alexandria, November 10.

Nebraska
Mrs. J. E. M. Thomson, president of the auxiliary to the Nebraska State Medical Association, was guest of honor at the

annual membership tea of the auxiliary to the Omaha-Douglas Counties Medical Society, Omaha, October 17. The auxiliary will place *Hygeia* in the public schools of these counties. At a meeting of the board of directors of the auxiliary to the Nebraska State Medical Association in Lincoln October 16 Dr. A. L. Miller, president of the association, was speaker.

Texas
The Tom Green Eight County Auxiliary met in San Angelo October 2. Mrs. Frank Clark of Abilene discussed legislation. This meeting was attended by sixty-five women representing clubs in San Angelo.

Tennessee
Miss Ellen Graham, of Boonville, read a paper at a meeting of the auxiliary to the Lincoln County Medical Society in Fayetteville recently, entitled "The Life and Work of a Country Doctor," which was published in *The Journal of the Tennessee State Medical Association* and was written by Miss Graham's father, now deceased.

Medical News

(PHYSICIANS WILL CONFER A FAVOR BY SENDING FOR THIS DEPARTMENT ITEMS OF NEWS OF MORE OR LESS GENERAL INTEREST: SUCH AS RELATE TO SOCIETY ACTIVITIES, NEW HOSPITALS, EDUCATION AND PUBLIC HEALTH.)

ARIZONA

Psittacosis in Arizona.—Three cases of psittacosis have been reported in Tucson, according to *Public Health Reports*, January 12. Two young adults of one family became ill October 7 and November 7, respectively, and a nurse on the first case became ill November 3. The family owned two love birds, which had been shipped from a pet shop in California, April 21, 1939. However, other birds in the same group were examined with negative results, it was stated.

CALIFORNIA

Society News.—The San Francisco County Medical Society was addressed, February 13, by Frances Tomlinson Gardner, librarian, Crummer room, University of California Medical School, on "Pedro Prat, Surgeon of the Spanish Conquest" and Dr. Arthur W. Meyer, Stanford University, "Historical Ideas Regarding Conceptomaterial Relations."—Dr. Frank E. Adair, New York, addressed a joint meeting of the radiologic section of the Los Angeles County Medical Association and the Los Angeles Cancer Society, January 30, on "Management of Breast Cancer."—At a meeting of the Los Angeles Society of Neurology and Psychiatry, January 17, the speakers were Drs. May E. G. Romm on "Notes on a Case of Exhibitionism in the Male" and Leo J. Adelstein, "Neurologic Divining Rods and Their Localizing Value."—At a meeting of the Hollywood Academy of Medicine, February 8, Dr. Robert R. Newell, San Francisco, discussed "Medical Uses of Radiation and Growth of the Specialty of Radiology."

COLORADO

Sewall Memorial Lecture.—Dr. Chester S. Keefer, Boston, delivered the Henry Sewall Memorial Lecture before the Medical Society of the City and County of Denver, January 30. His subject was "Hemolytic Streptococcal Infections: Their Importance in Acute and Chronic Disease."

Plans for the Care of Pneumonia.—Typing stations have been established in various sections of the state and plans adopted to distribute serum and sulfapyridine through the state department of health in the care of indigent patients, according to the *Rocky Mountain Medical Journal*. The program conforms with similar plans now carried out in many states and has the approval of the committee on pneumonia of the Colorado State Medical Society.

DISTRICT OF COLUMBIA

Annual Banquet of University Medical Society.—Harold W. Ickes, Secretary of the Interior, will be the principal speaker at the annual banquet of the George Washington Medical Society, Washington, February 17, which concludes the annual postgraduate clinic of George Washington University School of Medicine. A feature of the banquet will be the twenty year reunion of the class of 1920, which on this occasion intends to present a gift to the medical school.

ILLINOIS

Outbreak of Influenza.—Because more than 100 students and several teachers were ill from influenza, the Drummer Township high school, Gibson City, was closed recently.

Typhoid Carriers at Manteno State Hospital.—Ninety-three typhoid carriers were discovered in a survey at the Manteno State Hospital recently, newspapers reported on February 9. The survey was made following an outbreak of typhoid at the hospital causing the death of fifty-three persons.

No Auto Deaths in Galesburg.—Galesburg, a city of 29,000 population, did not have a traffic fatality in 1939, newspapers report. In Knox County outside of Galesburg there were twelve deaths as a result of automobile accidents. Galesburg has been carrying on an intensive campaign against these accidents. The police have concentrated on enforcing traffic

laws. Since schoolboy patrols went on duty this year at all the city schools, no pupil has been struck by a car.

Society News.—Dr. Willis C. Campbell, Memphis, Tenn., discussed "Internal Fixation of Fractures" before the Sangamon County Medical Society in Springfield, January 4.—At a meeting of the Logan County Medical Society on January 25, Drs. Ralph A. Reis and Harold J. Noyes, Chicago, discussed "Management of the Puerperium and Its Complications" and "Present Status of Dental Caries from the Standpoint of Knowledge of Etiology, Treatment and Dental Caries as an Index of Nutritional Adjustment" respectively.

Chicago

Clinical Meeting at Billings Hospital.—The clinical section of the Chicago Heart Association will meet at Billings Hospital, February 23. Dr. Arlie R. Barnes, Rochester, Minn., will be guest at the meeting. The following program has been arranged:

Drs. Dallas B. Phemister and Richard Sternheimer, Two Cases of Adhesive Pericarditis Treated Surgically.
Dr. Edith L. Potter, Embryological Background of Cardiac Malformations.
Dr. Andrew J. Brislen, The Clinical Measurement of Heart Size.
Dr. Wright R. Adams, Limitations of Objective Circulatory Measurements.
Dr. Louis Leiter, The Relation Between the Heart and Kidneys.
Dr. Barnes, Some Important Diagnostic Correlations of Electrocardiograms and Clinical Types of Heart Disease.

Medical Science and the Administration of Justice.

Dr. Alan R. Moritz, professor and head of the department of legal medicine, Harvard Medical School, Boston, will deliver the sixteenth Ludvig Hektoen lecture of the Frank Billings Foundation of the Institute of Medicine of Chicago, February 23, on "Medical Science and the Administration of Justice." On the same day there will be a medicolegal conference under the auspices of the institute's committee on local medicolegal problems with Dr. Oscar T. Schultz, Evanston, as chairman. The morning session will be held in the amphitheater of Cook County Morgue and will be given by the scientific staff of the county coroner's office. Albert J. Harno, dean of the college of law, University of Illinois, will preside at the afternoon session at the university's college of medicine. Speakers will include Capt. John I. Howe, Chicago Police Department; Dr. Israel Davidsohn; Fred E. Inbau, director of the Chicago Police Scientific Crime Detection Laboratory, and Benjamin C. Bachrach, public defender of Cook County. A tour will be made of the Chicago police laboratories, where there will be demonstrations of document examination, detection of deception by the lie detector, bombs and explosives, fingerprint examination and the study of blood stains, seminal stains and hair.

LOUISIANA

Graduate Medical Assembly—Dr. Matas Honored.—The fourth annual meeting of the New Orleans Graduate Medical Assembly will be held at the Roosevelt Hotel, February 26-29, in New Orleans. This year the assembly has been dedicated to Dr. Rudolph Matas, professor of general and clinical surgery, emeritus, Tulane University of Louisiana School of Medicine, New Orleans, in honor of his sixtieth year in active practice. The evening session of the first day will be in honor of Dr. Matas. Dr. Elliott C. Cutler, Boston, will speak on "Rudolph Matas—Dean of American Surgery" and Dr. Matas on "Along the Highways of Medicine in Louisiana." Included among the speakers on the scientific program will be:

Dr. William J. Dieckmann, Chicago, Types and Ambulatory Treatment of Patients with Toxemia of Pregnancy.
Dr. Henry L. Bockus, Philadelphia, The Clinical Status of Chronic Gastritis.
Dr. Eldridge L. Eliason, Philadelphia, Team Work in the Treatment of Biliary Disease.
Dr. Henry E. Michelson, Minneapolis, Treatment of Common Skin Diseases.
Dr. Shields Warren, Boston, Effects of Radiation on Tumors and Normal Tissues.
Dr. Quintan U. Newell, St. Louis, Radiation Therapy in Gynecology.
Dr. Francis M. Rackemann, Boston, The Pathology of Asthma.
Dr. James S. McLeester, Birmingham, Ala., Role of the Vitamins in Human Nutrition.

Dr. Marius N. Smith-Petersen, Boston, Arthroplasty of the Hip.
Dr. John A. Toomey, Cleveland, Chemotherapy in Acute Infectious and Contagious Diseases.
Dr. Fred M. Smith, Iowa City, Cardiac Therapy.

MEDICAL NEWS

JOUR. A. A.
FEB. 17.

MICHIGAN

State Society Appointments.—At a meeting of the council of the Michigan State Medical Society in Detroit, January 13-14, Dr. Ray S. Morrish, Flint, was appointed counselor of the sixth district to fill the unexpired term of Dr. Irving W. Greene, Owosso, who resigned, and Dr. Otto O. Beck, Birmingham, counselor of the fifteenth district to fill the unexpired term of Dr. George A. Sherman, Pontiac, who resigned. Drs. L. Fernald Foster, Bay City, and William A. Hyland, Grand Rapids, were reelected secretary and treasurer, respectively.

Personal.—Dr. William J. O'Reilly, Saginaw, was honored at a banquet given by the Saginaw County Medical Society, January 30, in recognition of his completion of fifty years in the practice of medicine. Dr. Charles E. Stewart, executive officer and president of the board of trustees of Battle Creek Sanitarium, was guest of honor at a banquet, January 17, marking his completion of fifty years in the practice of medicine. Dr. Thomas R. K. Gruber, Eloise, was presented with an honorary membership in the Wayne County local number 25, American Federation of State, County and Municipal Employees, at a testimonial dinner, January 25. Glenn Coleman, president of the local, was toastmaster at the dinner.

MINNESOTA

University News.—Mrs. John Dwan has given \$5,000 to the Minnesota Medical Foundation to support a program of the Human Serum Laboratory, which was established at the University of Minnesota Medical School, Minneapolis, in 1938. The laboratory is administered by a committee including Drs. Irvine McQuarrie, Paul F. Dwan and Erling S. Platou as a research and service project on the use of human serum for the prevention and treatment of certain infectious diseases. Dr. Albert V. Stoesser, associate professor of pediatrics, University of Minnesota Medical School, has received a grant-in-aid from the John and Mary R. Markle Foundation in support of his studies on water and electrolyte metabolism in intractable asthma.

Dr. Hilleboe Named to New Post of Medical Coordinator.—Other Appointments.—Dr. Herman E. Hilleboe, St. Paul, head of the bureau of crippled children, division of social welfare, has been appointed medical coordinator for the state department of social security, according to the Minneapolis Journal. Dr. Malvin J. Nydahl, since 1937 director of hygiene and health education in Minneapolis public schools, succeeds Dr. Hilleboe in the work for crippled children. The position of medical coordinator was created by the reorganization act of 1939. The appointment marks the beginning of an expanded program to correlate the medical services under the department of social security. Dr. Hilleboe will directly supervise all purely medical functions and establish working agreements with other state departments in joint medical rehabilitation programs, it was stated. Medical consultation will be provided for various state institutions and special assistance tendered where needed throughout the department. An advisory committee was also announced composed of Drs. Alfred W. Adson, Rochester, chairman; Ludwig L. Sogge, Duluth, and Chester Simons, Swanville; William A. Coventry, Duluth, and Edwin J. Stewart, Minneapolis. Ex officio members are Drs. Albert J. Chesley, St. Paul, secretary of the state board of health; Mr. R. R. Rosell, St. Paul, executive secretary of the Minnesota State Medical Association, Dr. Hilleboe and Walter H. Finke, chairman of the social security board and director of the social welfare division. Special technical subcommittees of three members each will be named later to act as consultants in special fields, such as orthopedics, tuberculosis and dental care. Dr. Hilleboe was formerly director of the division of tuberculosis and services for crippled children under the old state board of control. Announcement was also made of the appointment of Dr. William Rademaker, Evansville, as head of the bureau for aid to county tuberculosis sanatoriums.

NEW JERSEY

Society News.—Drs. John W. Gray, Newark, and George H. Lathrop, Morristown, addressed a stated meeting of the Academy of Medicine of Northern New Jersey, Newark, February 15, on "The Internist's Attitude Toward Infection in the Teeth, Sinuses and Tonsils." Dr. John S. Lundy, Rochester, Minn., will address a meeting of physicians and dentists at the academy, February 27, on "Intravenous Anesthesia," with discussion by Dr. Henry S. Ruth, Merion Station, Pa. Dr. Henry M. Thomas Jr., Baltimore, addressed the section on

medicine and pediatrics, February 13, on "Hypertension, Early Recognition and Management."—Dr. Harold E. Pardee, New York, addressed the Essex County Medical Society, Newark, February 8, on "Treatment of Arteriosclerotic Heart Disease" and Drs. Charles E. North, New York, and Elmer G. Wherry, Newark, on "Milk Standards."—Dr. William Wayne Babcock, Philadelphia, addressed the Bergen County Medical Society at Bergen Pines, February 13, on "Tumors of the Intestine."—Dr. Eugene P. Pendergraft, Philadelphia, addressed the Gloucester County Medical Society, Woodbury, January 18, on "The Role of the Radiologist in the Diagnosis of Intestinal Disease." Dr. Isidor S. Rabinowitz, Philadelphia, addressed the society, February 15, on "Blind Tract Disease."

NEW MEXICO

Public Health Meeting.—Dr. Roscoe P. Kandle, Clovis, was chosen president-elect of the New Mexico Public Health Association at its recent annual meeting and Dr. John C. Mitchell, Silver City, was installed as president. Dr. Frank W. Parker Jr., Santa Fe, was elected secretary. Guest speakers included Drs. Ethel C. Dunham of the U. S. Children's Bureau, Washington, D. C., and Platt W. Covington of the Rockefeller Foundation, Salt Lake City, Utah.

NEW YORK

Society News.—Dr. Samuel W. Clausen, Rochester, addressed the Onondaga County Medical Society, Syracuse, February 6, on "Obstruction of the Alimentary Tract."—Speakers at the winter meeting of the Madison County Medical Society in Oneida, January 18, were Drs. Sydney W. Stringer, on "The Vaginal Discharge"; Leon E. Sutton, "Early Local Care of Traumatic Wounds, with Special Reference to Wounds of the Face," and Earle E. J. Mack, "A Treatise on Vitamin Deficiencies." All are of Syracuse.—Dr. Plimpton Guptill, Rochester, addressed the Jefferson County Medical Society, Watertown, January 11, on diseases of the gallbladder.

New York City

Personal.—Dr. Morris L. Ogan, who recently retired after thirty-five years on the staff of the New York City Department of Health, was honored by his fellow workers at a dinner, January 6, at the Elks Club. Dr. Ogan was administrative assistant in the bureau of district health administration in charge of child and school health.

Friday Afternoon Lectures at the Academy.—The series of Friday afternoon lectures at the New York Academy of Medicine for the remainder of the season will be as follows:

- Dr. Soma Weiss, Boston, Types of Syncope and Their Treatment, March 1.
- Dr. Walter L. Niles, The Medical Treatment of Pain, March 8.
- Dr. Byron P. Stookey, What Neurological Surgery Can Do for the Relief of Intractable Pain, March 15.
- Dr. Arthur C. De Graft, An Evaluation of Some of the Newer Drugs, March 29.
- Dr. William P. Thompson, An Evaluation of Newer Laboratory Methods, April 5.
- Dr. Francis Carter Wood, A Critical Evaluation of the Diagnostic and Prognostic Tests for Cancer (The Bulkley Lecture), April 12.
- Dr. Walter O. Klingman, Recent Advances in Treatment of Somatogenic Phenomena in Psychoneuroses, April 19.
- Dr. Leo M. Davidoff, Recent Advances in the Diagnosis and Treatment of Diseases of the Central Nervous System, April 26.

Society News.—A symposium on recent advances in chemotherapy was presented before the Bronx County Medical Society January 17 by Drs. Reuben Ottenberg, who discussed streptococcal infection; Josephine B. Neal, meningitis; Cassius J. Van Slyke, gonorrhea, and Wheelan D. Suthli, pneumonia.—Dr. Herman J. Burman addressed the Bronx Otolaryngological Society January 23 on "Neck Infections."—William Cramer, Ph.D., addressed the Bronx Pathological Society January 16 on "The Etiology of Cancer."—Drs. Nathan B. Van Eten, President-Elect of the American Medical Association, and Terry M. Townsend, president of the Medical Society of the State of New York, addressed the Medical Society of the County of Queens January 30 on "The American Society of the Doctor Looks at the Citizen" respectively.—Dr. Eli Jefferson Browder, Brooklyn, delivered a Friday afternoon lecture, February 2, on "The Use and Abuse of Dehydration Agents in the Treatment of Head Injuries."—Speakers at the annual meeting of the New York Heart Association, January 23, were Drs. John G. Gibson II, Boston, on "Some Observations on the Blood Volume in Heart Disease" and Charles Sidney Burwell, Boston, "Studies of the Circulation During Pregnancy."

NORTH CAROLINA

Annual Postgraduate Course.—The University of North Carolina School of Medicine and the extension division are sponsoring their third annual postgraduate course in medicine in Charlotte. The series of lectures is as follows:

- Dr. Albert M. Snell, Rochester, Minn., Problems Presented by the Symptom Jaundice, February 6.
- Dr. Tom D. Spies, Cincinnati, Diagnosis and Treatment of Vitamin Deficiencies in Man, February 13.
- Dr. Walter E. Dandy, Baltimore, Mènière's Disease and Other Vertigoes: Cranial Neuralgias and Other Diseases and Lesions of the Cranial Nerves, February 20.
- Dr. Udo J. Wile, Ann Arbor, Mich., Diagnosis and Treatment of Syphilis, March 5.
- Dr. James H. Means, Boston, Thyroid and Other Endocrine Disorders, March 12.
- Dr. Emil Novak, Baltimore, Management of the Menopause, March 19.

OREGON

Changes in Health Officers.—Dr. David R. Rich, La Grande, has been appointed health officer of Union County, it is reported.—Dr. Lenor S. Goerke, McMinnville, has resigned as health officer of Yamhill County to go to Yolo County, Calif.; Dr. Hallister M. Stolte, Portland, is acting head of the department, newspapers report.

Personal.—Dr. Joseph B. Bilderback, Portland, was honored at a gridiron dinner given by about 300 friends at the University Club in Portland, January 5, in recognition of his recent election to the presidency of the American Academy of Pediatrics. Dr. Ralph A. Fenton, on behalf of the group, gave Dr. Bilderback a silver bowl.

PENNSYLVANIA

Special Meeting of Delegates.—A special meeting of the house of delegates of the Medical Society of the State of Pennsylvania will be held in Harrisburg, February 28, for consideration of a report on the proposed plan for the Medical Service Association of Pennsylvania.

Society News.—Drs. Dickinson Sergeant Pepper, Philadelphia, and Dale C. Stahle, of the state department of health, Harrisburg, addressed the Dauphin County Medical Society, Harrisburg, February 6, on "Treatment of Pneumonia" and "Pneumonia Problems in Pennsylvania" respectively.—Dr. Joseph C. Yaskin, Philadelphia, will address the Harrisburg Academy of Medicine, February 20, on "The Commoner Neuritides and Neuralgias, Their Diagnosis and Treatment."

Philadelphia

University Class Reunion.—The class of 1911 of the University of Pennsylvania School of Medicine will hold its thirtieth reunion this year instead of in 1941 in order to participate in the bicentennial celebration of the university to be held in September. The class will have a luncheon and dinner, September 19, at the Pine Valley Country Club, Clementon, N. J. Dr. Wilbur H. Haines, Philadelphia, is secretary.

Symposium on Allergy.—The Philadelphia County Medical Society held a meeting on allergy, February 14, with the following speakers: Drs. James Alexander Clarke Jr., on "Early Diagnosis of Asthma"; Austin T. Smith, "Management of the Nose and Paranasal Sinuses in Asthma," and Francis M. Rackemann, "Theory and Mechanism of Allergy." Dr. Richard A. Kern was the commentator.

Personal.—Mr. William H. Donner, founder of the International Cancer Research Foundation, received the honorary degree of doctor of laws from the University of Pennsylvania at the midyear convocation.—Dr. Milton Fraser Percival was recently elected president of the Medical Club of Philadelphia and Dr. Edward B. Krumbhaar of the College of Physicians of Philadelphia.

RHODE ISLAND

Society News.—Lester A. Round, Ph.D., state director of health, and members of his staff addressed a special midwinter meeting of the Rhode Island Medical Society in Providence, January 24, on "The State Department of Health, Its Organization and Functions."—Dr. Louis K. Diamond, Boston, addressed the Providence Medical Association, February 5, on "Treatment of Anemias in Infancy and Childhood with Special Reference to Splenectomy."—Dr. Milton C. Winternitz, New Haven, Conn., addressed a meeting of the Rhode Island Society of Neurology and Psychiatry, February 12, at the State Hospital for Mental Diseases, Howard, on "The Pathology of Arteriosclerosis."

TENNESSEE

Division of Tuberculosis in State Health Department.—A separate division of tuberculosis has been set up in the state department of health, it is reported. Dr. Roydon S. Gass, Franklin, who has been in charge of the field diagnostic service for tuberculosis for several years, will be in charge of the division, which was authorized by the 1939 legislature. The program of the new unit will consist of study and research, case finding and hospitalization. A new hospitalization service was recently instituted by the department (THE JOURNAL, Sept. 16, 1939, p. 1140).

Society News.—Dr. Edward L. Turner, Nashville, addressed the Nashville Academy of Medicine and Davidson County Medical Society, Nashville, January 9, on "Some Clinical Manifestations Resulting from Endamoeba Histolytica Infections."—Dr. William E. Chamberlain, Philadelphia, addressed the Chattanooga and Hamilton County Medical Society, January 18, on "Pitfalls in X-Ray Diagnosis."—Drs. James W. Bodley and Emmett R. Hall, Memphis, addressed the Madison County Medical Society, Jackson, January 2, on infections of the hand and arm, and the more common dermatoses, respectively.

Internships Available.—Announcement is made of two internships in pathology at the John Gaston Hospital, the teaching hospital of the University of Tennessee College of Medicine, Memphis. The term of service is for one year dating from July 1. Lodging, board, uniforms, laundry and \$20 a month are offered. After the internship one of the two men would be eligible for a two year appointment as assistant resident pathologist at the hospital and assistant in pathology in the medical school for the term July 1, 1941, to July 1, 1942. The hospital will furnish lodging, board, uniforms and laundry and the university a salary of \$32.50 a month. Following that period an appointment as resident pathologist will be available for the period July 1, 1942, to July 1, 1943. Lodging, board, uniforms and laundry will be furnished by the hospital and a salary of \$65 a month by the university. Investigative work will be encouraged, according to the announcement. The John Gaston Hospital is a general hospital of 550 beds, with annual admissions of 15,976 to the hospital and 155,758 visits to the outpatient department. Applicants are requested to submit full information, including name in full, place of birth, present address, age, sex, nationality, religion, whether he is single or married, academic training, date of finishing present appointment, date on which service could begin, two recommendations and a photograph. Dr. Harry C. Schmeisser is chief of the division of laboratories at the hospital.

UTAH

Resolutions Concerning Licensure.—The Utah State Examining Committee of Physicians and Surgeons of the Department of Registration at a meeting, January 17, adopted a resolution requiring candidates for licenses who have had the major portion of their education in foreign schools to furnish satisfactory evidence of moral and educational qualifications and to pass the state board examinations. The committee also approved a resolution requiring all applicants to be graduates of medical schools approved by the department of registration. Finally the committee recommended to the director of the department of registration that applicants for reciprocal licenses be required to prove that equal privileges are granted by the state or country from which they come. It was pointed out that certain states and foreign countries grant reciprocal licenses only after a physician has practiced a certain number of years. The Utah director was therefore urged not to grant licenses on more favorable terms than those on which such a license would be granted in the state or country in which the applicant is domiciled.

VIRGINIA

McGuire Lectures and Spring Clinic.—The annual Stuart McGuire Lectures of the Medical College of Virginia will be delivered, April 16-17, by Dr. C. Frederic Fluhmann, San Francisco. Dr. Fluhmann's subjects will be "Anesthesia and Analgesia in Obstetrics" and "The Problem of Abnormal Uterine Bleeding." The annual spring postgraduate clinics will be held, April 17, on the general subject "Toxemias of Pregnancy." The speakers will be Drs. Nicholson J. Eastman and Louis H. Douglass, Baltimore; Tiffany J. Williams, Charlottesville, and Francis Bayard Carter, Durham, N. C.

SOCIETY NEWS.—A symposium on diseases of the kidney was presented before the King County Medical Society, Seattle, January 22, by Drs. Frank J. Clancy, Alexander B. Hepler, Alexander H. Peacock and Ole A. Nelson. A symposium on biliary disease was presented on February 5 by Drs. Fred J. Jarvis, Carl S. Leede and William C. Speidel.—Dr. Frank Perlman, Portland, Ore., addressed the Whitman County Medical Society, February 1, on "Phases of Allergy of Interest to the General Practitioner."

WYOMING

Personal.—Dr. Eugene G. Ewing has resigned as health officer of Albany County and Dr. Lee W. Storey, Laramie, has been appointed his successor.—Dr. Thomas B. Croft, Lovell, was elected president of the Northwest Wyoming Medical Society at a recent meeting in Lovell.

PUERTO RICO

University News.—Dr. Frederick J. Brady, of the U. S. Public Health Service, has been detailed to the School of Tropical Medicine conducted at the University of Puerto Rico, San Juan, under the auspices of Columbia University to conduct research in parasitology for six months.—Dr. Guillermo Ruiz Cestero, San Juan, gave a seminar lecture at the School of Tropical Medicine, January 18, on "Fluorography: A New Method of Obtaining Films of the Chest at a Very Low Cost." Dr. Manuel A. Astor, Arecibo, was the speaker, January 11, on "Fractures of the Elbow."—At the annual meeting of the Puerto Rico Medical Association in December the house of delegates approved a resolution expressing its satisfaction and pride in the work of the School of Tropical Medicine and offered support for future undertakings.

GENERAL

Tuberculosis Fellowships Adjourned.—The *Bulletin* of the National Tuberculosis Association announces that the secretariat of the International Union Against Tuberculosis, in agreement with the National Italian Federation Against Tuberculosis, has decided to adjourn competition for six fellowships at the Carlo Forlanini Institute because of European conditions. Fourteen applications had been received from twelve countries, including the United States.

Red Cross Meeting Plans Changed.—The time and place of the annual meeting of the American Red Cross, which was to be held in Atlanta, Ga., May 13-16, have been changed to Washington, D. C., May 6-8. According to a statement by the national chairman, Norman H. Davis, the exceptional pressure occasioned by the European situation has placed such an added burden on the national officers that absence from Washington for four or five days is unwise.

Rheumatism Congress Postponed.—The American Committee of the Ligue internationale contre le rhumatisme and the American Rheumatism Association announce that the seventh International Congress on Rheumatic Diseases, which was to have been held June 8-10 in Philadelphia, Boston and New York, has been postponed "until the European horizon widens." Dr. Ralph Pemberton, Philadelphia, is president of the international league and Dr. Philip S. Hench, Rochester, Minn., of the American Rheumatism Association. Dr. Loring T. Swaim, Boston, is secretary of the American association.

Dr. Gudakunst Medical Director of Infantile Paralysis Foundation.—Dr. Don W. Gudakunst, U. S. Public Health Service, has been appointed medical director of the National Foundation for Infantile Paralysis, effective February 1. He will have his office at the foundation's headquarters at 120 Broadway, New York. Dr. Gudakunst graduated at the University of Michigan Medical School, Ann Arbor, in 1919. He served for many years with the Detroit Department of Health and later as commissioner of health of Michigan. He was also professor of preventive medicine and public health at Wayne University College of Medicine, Detroit.

Goiter Prize Competition.—The American Association for the Study of Goiter again offers the Van Meter Prize Award of \$300 and two honorable mentions for the best essays concerning original work on problems related to the thyroid gland. The essays may cover clinical or research investigations, should not exceed 3,000 words, and must be presented in English. A typewritten double spaced copy must be sent not later than March 15 to the corresponding secretary of the association, Dr. William Blair Mosser, 133 Biddle Street, Kane, Pa.

A place will be reserved on the program of the annual meeting for presentation of the prize award essay by the author. It is possible for him to attend. The essay will be published in the annual proceedings of the association, but this will not prevent its further publication in any journal selected by the author. The next meeting of the association will be in Rochester, Minn., April 15-17. The winner of the 1939 competition was Dr. Theodore L. Althausen, associate professor of medicine, University of California Medical School, San Francisco.

Orthopsychiatric Meeting.—The seventeenth annual meeting of the American Orthopsychiatric Association will be held on February 22-24 at the Hotel Statler, Boston. Among the papers to be presented are the following:

- Dr. William Healy, Boston, Psychiatry and the Treatment of Young Offenders in the Plans of the Committee of the American Institute.
- Dr. Joseph J. Michaels, Boston, Parallels Between Persistent Enuresis and Delinquency.
- Dr. Joseph Lander, Hawthorne, N. Y., A Study of Traumatic Emotional Factors in the Backgrounds of 116 Delinquent Boys.
- Dr. Everett S. Rademacher, New Haven, Conn., Democracy and Mental Hygiene in the Home.
- Dr. Lawson G. Lowrey, New York, Personality Distortion and Early Institutional Care.
- Dr. Fred Temple Burling, Ridgewood, N. J., The Role of the Professionally Trained Hygienist.
- Dr. Charles Bradley and Margaret Bowen, R.N., East Providence, R. I., Amphetamine (Benzedrine) Therapy of Children's Behavior Disorders.

Annual Report of Commonwealth Fund.—Completing its twenty-first year, the Commonwealth Fund in its annual report recalls that its work was begun with gifts for war service and relief and that part of its income was devoted to relief and reconstruction for more than ten years. Now all its major objectives are threatened by war; many of its activities have been disrupted for the time being. Gradually changing its emphasis to American health, the Fund has since 1918 appropriated for its main interests more than \$13,500,000 to the promotion of physical health; nearly \$7,000,000 for mental health, and for fellowships to bring British graduate students to American universities, \$3,250,000. Appropriations for the year ended Sept. 30, 1939, amounted to \$1,919,908.73, of which about two thirds was for the promotion of health through medical education, medical research, public health and the rural hospital program. To aid in the development of public health activities in Oklahoma, Alabama, Tennessee, Mississippi and Massachusetts, the Fund appropriated \$356,619.72. This appropriation also covered fellowships for physicians and nurses to study at Harvard, Tulane and Vanderbilt universities and at Tufts College. The rural hospital program sponsored by the Fund now includes ten hospitals completed, two in the planning or construction stage and one not built by the Fund but receiving cooperation. The appropriation for this division, \$491,606.67, includes not only construction but fellowships for physicians and hospital personnel, support of a training course for hospital administrators at the University of Chicago and technical advisory service. Two of the older hospitals in this group are now so overloaded that plans are being made to enlarge them. Mental hygiene, a major preoccupation of this foundation from the beginning, claimed an appropriation of \$193,329. The Fund's method in this field at present is to encourage the interpretation of psychiatry and clinical medicine, primarily in the practice of psychiatry and clinical medicine, for graduate training and through establishment of clinical teaching facilities which bring a psychiatric point of view into the pediatric service. The Fund supports the development of psychiatry at the University of Louisville and the Committee for Mental Hygiene; a teaching clinic and psychiatric unit for children at the University of Minnesota; a new similar unit at Stanford University School of Medicine; and fellowships at various universities and hospitals. One of the casualties of the war is in this field. The London Child Guidance Clinic and Training Center, supported by the Fund, has closed for the duration of the war; the Child Guidance Council has moved its headquarters to Bath and taken up emergency duties in addition to its usual program. Fellowships granted to British students to study in the United States have also been interrupted in many cases and four American students who planned to study abroad have had to postpone the trip or transfer their work elsewhere. Few new grants for medical research were made, the report stated, the greater part of the funds available for this purpose having been pledged previously. The new ones included funds for two ultracentrifuges at Harvard University for the study of protein chemistry; studies of kidney function, chemical factors in resistance to disease and leukemia.

Jan. 13, 1940.

Food Rationing Begun

In this war, as in the last, the allies hold command of the sea. The submarine campaign has failed and the losses of ships from the strewing of the sea with mines are too small to affect commerce seriously. This ruthless procedure has caused more losses to neutrals than to the allied powers. Britain imports a large part of the food supply and there is plenty of shipping to bring it. But the war is a strain on the national resources. The importation of munitions on a large scale and the movement of troops limit the shipping which can be used for food. Moreover, millions of fighting men withdrawn from production have to be fed. It is not surprising that rationing of food has been introduced. The object is that all, rich or poor, shall be able to obtain sufficient food. There is plenty of food in the country, but some control is necessary in the case of a few favorite foods. Their rationing is only a small inconvenience, as there are plenty of alternatives. Only butter, bacon, ham and sugar have been rationed, but in February meat will be added to the list.

The weekly allowance of butter is only 4 ounces to a person, about half the normal consumption. But this is not important nutritionally, as all other fats are unrestricted and there is an excellent margarine, indistinguishable from butter and containing vitamins. The weekly allowance of bacon or ham is also 4 ounces. This again is unimportant, as there are so many alternatives. The allowance of sugar is 12 ounces a week. Syrup, treacle, jam and confections are not rationed. Meat will be rationed not by quantity but by price, the weekly allowance being 36 cents. This restriction does not affect nutrition, as there are many unrationed sources of protein—fish, poultry, game, milk and cheese. Moreover, the edible offals—liver, kidney, sweetbreads—are unrationed. A main cause for this mild rationing is that the government has decided that the fighting services must be better fed than civilians are in time of peace.

The Pelvic Osteo-Arthropathy of Pregnancy

Loosening of the pelvic joints in pregnancy to facilitate labor is an observation which goes back to Hippocrates, but it has generally been regarded as only physiologic, though Joel E. Goldthwait (*THE JOURNAL*, Aug. 31, 1907, p. 768) and others drew attention to the frequent part played by softening of the sacro-iliac joints in the production of the backache of pregnancy. To the Section of Obstetrics and Gynecology of the Royal Society of Medicine, Prof. James Young made a communication based on forty-two cases of pelvic osteo-arthropathy in pregnancy, of which thirty-four occurred in a series of 4,512 pregnant women (0.75 per cent). The symptoms were pain and tenderness in the sacro-iliac and pubic regions coming on during pregnancy and aggravated by walking, which was often difficult and in seven cases impossible. There was frequently a limp or waddle in the gait. In some cases the pain and tenderness were located in one sacro-iliac joint. In cases of severe locomotor difficulty there were often pain and tenderness along the line of the adductor muscles of the thigh. A number of patients dated the symptoms from some trauma, which might be trivial, such as a slip or a fall. In one case bending down to tie a shoe lace was immediately followed by acute symptoms. In thirty-three cases the time of onset of the symptoms was recorded. In thirty-two they arose during

pregnancy and in one ten days after delivery, when the patient got out of bed. The average time of onset was the twenty-sixth week of pregnancy, the earliest the eighth week and the latest the thirty-sixth. Thirteen of the patients were primiparas.

Professor Young could not find that the symptoms bore any relation to the increase of pubic separation, as other workers have suggested. Many cases with severe symptoms showed no greater widening than is found ordinarily in pregnancy without symptoms. But when pubic symptoms were severe a gliding movement could easily be detected at the joint when grasped between a finger in the vagina and the thumb over the symphysis, and the patient was asked first to stand on one foot and then on the other.

Why does a condition which must be regarded as essentially physiologic sometimes pass over into the pathologic? In five of the thirty-four cases there was a definite relation to a minor accident. Lowered tone of the muscles supporting the joints may in some cases render them liable to damage. It may be significant that fifteen of the thirty-four women suffered from associated conditions such as toxemia and pyelitis. The alteration of the spinal curves consequent on the passing forward of the center of gravity of the body because of the enlarging uterus transmits the body weight along new lines and may create stresses in the pelvic joints and muscles. Finally, an endocrine origin is given for the softening of the pelvic joints.

The treatment in mild cases is the provision of a strong abdominopelvic belt and restricted exercise. In more severe cases rest in bed for from one to three weeks may give so much relief as to make walking comfortable with the support of the belt. In the worst cases complete rest in bed till delivery is necessary. In such the hammock, as used for the treatment of fractured pelvis, is of great value. These women cannot tolerate the gentlest movement in bed, as in placing the bedpan. After delivery the treatment varies with the case. In mild cases the symptoms disappear in the ordinary lying-in period. In severer cases rest in bed for two or three weeks may be required, followed by a supporting belt for several months. In the worst cases the hammock should be continued for at least a month and possibly for several months.

OSLO

(From a Special Correspondent)

Jan. 3, 1940.

The Problem of Induced Abortions

In the lay as well as in the medical press during the last few years, the discussion of the ethics of induced abortions seems to have been fruitless. At any rate no concrete measure for the reform of existing legislation has emerged. And the fanatics at both extremes have been most successful in exasperating the man in the street as well as each other. A study of the problem was presented last autumn to the Norwegian Medical Society by Dr. Johan Haffner, who is attached to Akers Hospital, Oslo. Part of it concerns facts, part proposals.

In the Akers Hospital in the seven year period 1932-1938, 970 cases of abortion were dealt with. Seventy-nine per cent of the women were married, and more than three fourths of these married women had already given birth to one child or more. Only in 3.2 per cent of the total was the age of the patient under 20, all of which data go to invalidate the popular fallacy that the criminal induction of abortion is mainly the concern of irresponsible, juvenile, unmarried women. Sixty per cent of these abortions were afebrile. There were fifteen deaths, an average of two a year. Dr. Haffner calculated that in the public hospitals alone some seven or eight women die every year in Oslo of abortion. In as many as eighty-three of the 131 cases in which the induction of abortion was confessed to, a catheter had been employed, usually by the woman herself.

Dr. Haffner would stop the trouble at its source, i. e. by the teaching of birth control by competent persons. He suggests that, before discharge from hospital, every patient who has been treated for abortion should be given instructions as to how to prevent pregnancy in the future. The pornographic and usurious conditions under which catheters and allied devices are hawked round to the public should be stamped out by the authorities, who should themselves provide the advice and other help needed by so many women in these circumstances. It is gratifying to note that prosecutions have already been instituted against the worst offenders in this field.

At a recent meeting in Oslo of the Norwegian Medical Society, a resolution was adopted to the effect that this society sees in the illegal interruption of pregnancy a medical problem which is serious. The resolution proceeds: "As a contribution to the campaign against this evil, the society recommends that the number of health centers for maternity and child welfare be increased and their activities extended to the teaching of the physiology of sex and of contraception so that this too comes under medical control. The society also finds that both humane and medical considerations indicate an extension of legal opportunities for interrupting pregnancy when there are cogent arguments for doing so." This resolution is the more important as the Norwegian Medical Society is fairly representative of the whole of the Norwegian medical profession, although less than half of the doctors in Norway are members of this society.

A New Law Affecting Servants

A law was recently made by which persons suffering from infections of a contagious nature are not allowed to enter the domestic service. All servants must pass medical examinations, which are free of charge and which will be repeated at specified intervals. The results of the examinations will be kept in special records. The penalty for infraction of the law, both patrons and servants, is a fine up to 500 lire (\$25).

Lecture on Venereal Lymphogranuloma

Prof. A. Midana, of Turin, in a lecture before the Società di gastro-enterologia of that city, discussed venereal lymphogranuloma. All varieties of the anorectocolonic form, which is the most frequent, should be grouped under the name of infiltrating rectitis. Often the rectal lesions progress to the lower segments of the large intestine. It is possible that certain forms of colonic diseases which are diagnosed as ulcerous colitis are forms of inguinal lymphogranuloma with extension to the colon. The formation of fistulas is a grave complication. The pathogenesis of the condition is unknown. The various theories agree that inoculation of the rectal walls takes place either directly through the mucosa or through the neighboring lymphatic regions. The development of either the hypertrophic or the stenotic form of the disease depends on the mechanism by which contagion takes place, which in turn depends on the sex of the patient.

Test for Liver and Renal Functions

Prof. E. Macchia, of Naples University, in a lecture before the Accademia medica di Naples, reported a simple technic for determination of indole in the blood as a test for liver and renal functions. An intravenous injection of a 2 per thousand indole solution is slowly administered to patients during fasting. The solution is prepared in physiologic solution of sodium chloride. The dose is 1 cc. of the solution for each 6 Kg. of body weight. Blood for determining indole is taken ten minutes after the injection and again 120 minutes after it. The first blood is withdrawn for diagnosis of the detoxicating functions

of the liver, the second one for diagnosis of the emunctory functions of the kidneys. The amount of indole in the blood serum of the first sample of blood varies between 0.15 and 0.2 mg. for each thousand cubic centimeters of blood if the detoxicating functions of the liver are normal. The figures are higher if the functions of the liver are poor. The amount of indican in the blood of the second sample varies between 1.4 and 1.5 mg. for each thousand cubic centimeters of blood if the emunctory functions of the kidney are good. The more acute the emunctory dysfunctions of the kidney, the higher the figures of indicanemia. The test is reliable. The amount of indole in the blood of patients who are suffering from renal diseases or uricacidemia is normal after indole loading, whereas it is increased in patients with liver detoxicating dysfunction.

Treatment of Malaria

Professor Pansini reported to the Accademia della scienza mediche e chirurgiche, of Naples, the results of different treatments in more than 3,000 cases of benign malaria in Italians coming home from Africa. The different treatments used in various groups of patients were epinephrine, atabrine, quinine and antimony tartrate. He concluded that the evolution of malaria can be favorably modified by any of the various treatments which are commonly employed.

No treatment, either alone or in association with another, controls malaria unless a certain time elapses and immunity develops. Radical changes in the environment and living habits of the patients, such as change of climate, rest and adequate food, are important factors in accelerating the establishment of immunity in malaria. Quinine has specific action in controlling the attack but does not prevent malarial recurrences. When the drug is administered over a long period, reappearance of malaria is prevented. However, attacks frequently reappear after discontinuation of the drug. The speaker believes that quinine has a specific biologic action by which the pyretogenic properties of plasmodia are neutralized. Atabrine prevents recurrences for longer periods than those induced by quinine. Epinephrine neither prevents nor prolongs the intervals between attacks. Sometimes the attacks take place more often during epinephrine treatment than before it. The effects of epinephrine are better when it is administered in association with other drugs than when given alone. The results of the antimony or potassium tartrate treatment are inconstant. The alternate administration of some drugs of antimalarial value gives satisfactory results.

Marriages

MYERS BOWMAN DEEMS, Huntington, Ind., to Miss Florence Esther Woods, of Evansville, in Orlando, Fla., Dec. 28, 1939.
JOSEPH JAMES SOFRANEC JR., Youngstown, Ohio, to Miss Jean Louise Lumpp, of Sharon, Pa., in New Orleans, January 6.
JULIAN KENNETH WELCH JR., Memphis, Tenn., to Miss E. Lucille Mount, of Trezevant, Tenn., Dec. 17, 1939.
ROBERT LEE ROBINSON, Mars Hill, N. C., to Miss Sara Hel Willingham, of Atlanta, Ga., in December 1939.
KENT A. DEWEY, Grand Rapids, Mich., to Miss Margaret McGregor, of Lynnville, Tenn., Dec. 24, 1939.
CHARLES BARRETT KENNEDY to DR. REBECCA STUBBS WRIGHT, both of New Orleans, Dec. 20, 1939.
OSCAR EDGEWORTH BLOCH JR. to Miss Jean Russell, both of Louisville, Ky., in December 1939.
LELAND H. DAME to Miss Mary Lec Price, both of West Palm Beach, Fla., Dec. 25, 1939.
GEORGE R. O'DANIEL to Miss Esther Cordell, both of Hartsville, S. C., Dec. 20, 1939.
JOSEPH M. RUDA to Miss Florence Rudzinski, both of Chicago, Nov. 23, 1939.
S. CHARLES FREED to Miss Shirley Kolinsky, both of Chicago, February 11.

Deaths

Frank Hicks Walke ☉ Shreveport, La.; Baltimore Medical College, 1912; formerly secretary of the Shreveport Caddo Parish Medical Society; for many years secretary-treasurer of the Tri-State Medical Association (Texas, Arkansas, Louisiana); member of the parish school board; held a commission in the U. S. Navy and was a member of the medical advisory board during the World War; at one time parish health officer; was physician in chief to the Home for the Aged; for many years federal jail physician; member of the staffs of the Highland Sanitarium, Schumpert Memorial Sanitarium and the Pines Sanatorium; member of the board of trustees of Dodd College; aged 53; died, Dec. 21, 1939.

John Francis Condon ☉ Newark, N. J.; Long Island College Hospital, Brooklyn, 1901; past president of the Essex County Medical Society; member of the state board of medical examiners; fellow of the American College of Surgeons; attending gynecologist to the Essex County Isolation Hospital, Belleville; chief, department of obstetrics and gynecology and medical director, St. James Hospital; attending obstetrician to the Newark City Hospital, consulting obstetrician to the Irvington (N. J.) General Hospital, Hospital of St. Barnabas and for Women and Children, Presbyterian Hospital, Newark and St. Mary's Hospital, Orange; aged 67; died, Dec. 8, 1939, of coronary thrombosis.

Carl Richard Keppler, Newark, N. J.; Columbia University College of Physicians and Surgeons, New York, 1898; member of the Medical Society of New Jersey; formerly professor of orthopedics at the Fordham University School of Medicine, New York; served at various times and in different capacities on the staffs of the Yorkville Hospital, Harlem Hospital, Sydenham Hospital and the Fordham Hospital, New York; St. Elizabeth's Hospital, Elizabeth, and Somerset Hospital, Somerville; aged 62; died, Dec. 27, 1939, of cerebral hemorrhage.

Alfred Bielschowsky ☉ Hanover, N. H.; Universität Leipzig Medizinische Fakultät, Saxony, Germany, 1894; professor of ophthalmology at Dartmouth Medical School; formerly professor of ophthalmology at the University of Breslau, Germany, and member of the faculties of the Universities of Marburg and Leipzig; member of the New England Ophthalmological Society; director of the Dartmouth Eye Institute; aged 68; died, January 6, at the Jewish Hospital, Brooklyn, following an operation for brain tumor.

Seneca Egbert ☉ Wayne, Pa.; University of Pennsylvania Department of Medicine, Philadelphia, 1888; emeritus professor since 1932 and professor of hygiene from 1916 to 1931 at his alma mater; professor of hygiene from 1893 to 1916 and dean from 1898 to 1916, Medico-Chirurgical College of Philadelphia; professor of hygiene, Temple University School of Medicine, Philadelphia, from 1896 to 1899; author of "A Manual of Hygiene and Sanitation" published in eight editions and "Personal Hygiene for Nurses"; aged 76; died, Dec. 6, 1939.

Le Roi Goddard Crandon ☉ Boston; Harvard Medical School, Boston, 1898; fellow of the American College of Surgeons; instructor of surgery at his alma mater from 1903 to 1918; on the staffs of the Whidden Memorial Hospital, Everett, Chelsea (Mass.) Memorial Hospital and the Home Memorial Hospital, New London, Conn.; author of "Surgical After-Treatment" published in 1911; aged 66; died, Dec. 27, 1939.

James Douglas Crane ☉ Ishpeming, Mich.; College of Physicians and Surgeons, Baltimore, 1914; past president of the Marquette-Alger Counties Medical Society; fellow of the American College of Surgeons; served during the World War; on the staff of the Ishpeming Hospital; aged 47; died, Dec. 18, 1939, in the Columbia Hospital, Milwaukee, of coronary disease and chronic hypertension.

Roy Ernst Mitchell ☉ Eau Claire, Wis.; University of Minnesota College of Homeopathic Medicine and Surgery, Minneapolis, 1901; member of the American Psychiatric Association; past president and secretary of the Eau Claire and Associated Counties Medical Society; on the staff of the Luther Hospital; aged 63; died, Dec. 12, 1939, of coronary occlusion.

Ernest Mitchell Fuqua, Pulaski, Tenn.; Vanderbilt University School of Medicine, Nashville, 1911; member of the Tennessee State Medical Association; served during the World War; at one time superintendent of the Protestant Hospital, Nashville; member of the state board of health; aged 58; died, Dec. 31, 1939, in St. Thomas Hospital, Nashville.

Kenneth Cameron, Westmount, Que., Canada; McGill University Faculty of Medicine, Montreal, 1887; fellow of the American College of Surgeons; served during the World War; formerly lecturer in clinical surgery at his alma mater; on the staff of the Montreal General Hospital for many years; aged 76; died, Dec. 25, 1939, of heart disease.

George McClellan Liston ☉ Baldwin City, Kan.; Medical College of Indiana, Indianapolis, 1892; Hospital College of Medicine, Louisville, Ky., 1896; past president of the Douglas County Medical Society; aged 75; died, Dec. 18, 1939, in the University of Kansas Hospital, Kansas City, of prostatic hypertrophy and heart disease.

Edson Elisha Gadd ☉ Des Moines, Iowa; Eclectic Medical Institute, Cincinnati, 1897; Bennett College of Eclectic Medicine and Surgery, Chicago, 1903; College of Physicians and Surgeons of Chicago, School of Medicine of the University of Illinois, 1905; aged 70; died, Dec. 9, 1939, of coronary thrombosis.

Francois Louis Demers, Montreal, Que., Canada; School of Medicine and Surgery of Montreal, Faculty of Medicine of the University of Laval at Montreal, 1909; formerly member of the city council and member of the medical staff of the city health department; served during the World War; aged 57; died, Dec. 26, 1939.

Todd Caris, Mount Gilead, Ohio; Starling Medical College, Columbus, 1895; member of the Ohio State Medical Association; for many years county coroner; secretary of the Morrow County Medical Society; served during the World War; aged 68; died, Dec. 28, 1939, in the Marion (Ohio) City Hospital of myocarditis.

Arthur Henry Domann ☉ Orange, Calif.; College of Physicians and Surgeons, medical department of the University of Southern California, Los Angeles, 1911; fellow of the American College of Surgeons; on the staffs of the Orange County Hospital and St. Joseph Hospital; aged 60; died, Dec. 11, 1939.

Thomas Vincent McLaughlin, Wilkes-Barre, Pa.; Medico-Chirurgical College of Philadelphia, 1906; member of the Medical Society of the State of Pennsylvania; served during the World War; aged 60; for many years on the staff of the Mercy Hospital, where he died, Dec. 10, 1939.

William Rado ☉ Newark, N. J.; Magyar Királyi Pazmany Petrus Tudományegyetem Orvosi Fakultasa, Budapest, Hungary, 1918; member of the National Gastrological Association; aged 46; died, Dec. 30, 1939, in the Beth Israel Hospital of gangrenous appendicitis.

Robert Ferguson, West Hartford, Conn.; Yale University School of Medicine, New Haven, 1903; fellow of the American College of Surgeons; formerly on the staff of the Copper Queen Hospital, Bisbee, Ariz.; aged 64; died, Dec. 12, 1939, of coronary embolism.

George E. Kerr ☉ Chattanooga, Okla.; Detroit College of Medicine, 1894; past president of the Comanche County Medical Society; aged 72; died, Dec. 25, 1939, in the Wichita General Hospital, Wichita Falls, Texas, of heart disease and bronchopneumonia.

James Thomas Breedlove, St. Louis; Meharry Medical College, Nashville, Tenn., 1912; aged 61; on the staffs of St. Mary's Infirmary, Homer G. Phillips Hospital and the Peoples Hospital, where he died, Dec. 31, 1939, of pneumonia and ruptured appendix.

Frank Laird Kennedy, Camden, N. J.; Hahnemann Medical College and Hospital of Philadelphia, 1928; for many years on the staff of the West Jersey Homeopathic Hospital; aged 35; died, Dec. 3, 1939, in the Hahnemann Hospital of typhoid.

John Krupp Hedrick, Telford, Pa.; Hahnemann Medical College and Hospital of Philadelphia, 1898; for many years president of the board of health, and secretary of the board of education; aged 69; died, Dec. 12, 1939, of cerebral hemorrhage.

James Madison Hamilton, Los Angeles; University of Vermont College of Medicine, Burlington, 1893; member of the Vermont State Medical Society; served during the Spanish-American and World wars; aged 71; died, Dec. 10, 1939.

Mathew Earl O'Keefe ☉ Council Bluffs, Iowa; John A. Creighton Medical College, Omaha, 1906; fellow of the American College of Surgeons; on the staff of the Mercy Hospital; aged 58; died, Dec. 6, 1939, of coronary thrombosis.

Don Rhodolph Flower, Park Falls, Wis.; Bennett College of Eclectic Medicine and Surgery, Chicago, 1894; for many years member of the Park Falls city council, and health officer; aged 88; died, Nov. 14, 1939, of senility.

DEATHS

JOUR. A. M. A.
Feb. 17, 1939

- Clarence Henderson, Lind, Wash.; College of Physicians and Surgeons of Chicago, School of Medicine of the University of Illinois, 1906; for many years member of the school board, and health officer; aged 70; died, Dec. 1, 1939.
- Alice Rogers Easby, Media, Pa.; Woman's Medical College of Pennsylvania, Philadelphia, 1884; member of the Medical Society of the State of Pennsylvania; aged 79; died, Dec. 29, 1939, of arteriosclerosis and heart disease.
- Thomas Fulton McConaghie, Oakdale, Ill.; St. Louis University School of Medicine, 1904; member of the Illinois State Medical Society; aged 67; died, Dec. 29, 1939, in St. Mary's Hospital, Centralia, of pneumonia.
- Theodore Henry Wheeler, Los Angeles; Eclectic Medical College of Indiana, Indianapolis, 1903; Central College of Physicians and Surgeons, Indianapolis, 1904; served during the World War; aged 69; died, Nov. 22, 1939.
- Joseph Johnson Waller, Oliver Springs, Tenn.; Southern Medical College, Atlanta, Ga., 1892; member of the Tennessee State Medical Association; aged 72; died, Dec. 8, 1939, of coronary thrombosis and hypertension.
- James McCrea, Fulda, Minn.; McGill University Faculty of Medicine, Montreal, Que., Canada, 1894; past president of the Murray County Medical Society; aged 76; died, Dec. 19, 1939, of carcinoma of the rectum.
- George William Krick, West Pittston, Pa.; Hahnemann Medical College and Hospital of Philadelphia, 1913; served during the World War; aged 50; died, Dec. 17, 1939, in the Homeopathic Hospital, Reading.
- Charles Edward Fawcett, Stewartville, Minn.; Northwestern University Medical School, Chicago, 1893; bank president and president of the school board; aged 70; died, Dec. 8, 1939, of coronary thrombosis.
- Ephraim W. Bogardus, Geneva, N. Y.; University of Buffalo School of Medicine, 1883; member of the Medical Society of the State of New York; aged 86; died, Dec. 17, 1939, of chronic myocarditis.
- James Otis Carrington, Darby, Pa.; Howard University College of Medicine, Washington, D. C., 1913; on the staff of the Mercy Hospital, Philadelphia; aged 56; died, Dec. 2, 1939, of coronary occlusion.
- Philip Aloysius Lonergan, Dickson, Pa.; University of Pennsylvania School of Medicine, Philadelphia, 1909; served during the World War; aged 54; died, Dec. 16, 1939, of heart disease.
- James Aloysius Mulligan, Union City, N. J.; Atlantic Medical College, Baltimore, 1909; aged 60; died, Dec. 7, 1939, in St. Mary's Hospital, Hoboken, of arteriosclerosis and heart disease.
- Walter J. Dickson, Nashville, Ga.; Atlanta College of Physicians and Surgeons, 1906; county physician; member of the school board; aged 61; died, Dec. 21, 1939, of typhus fever.
- Vernon Voorhees Rood, Grass Valley, Calif.; College of Physicians and Surgeons, Los Angeles, 1916; member of the California Medical Association; aged 60; died, Nov. 16, 1939.
- John Fred Yonkman, Grand Rapids, Mich.; University of Michigan Medical School, Ann Arbor, 1923; served during the World War; aged 45; died, Dec. 14, 1939, of brain tumor.
- Gisle Bjornstad, Minneapolis; University of Minnesota College of Medicine and Surgery, Minneapolis, 1894; aged 72; died, Dec. 29, 1939, of hypertension and coronary disease.
- Francis Howard Finley, Finleyville, Pa.; College of Physicians and Surgeons, Baltimore, 1895; bank president; aged 68; died, Dec. 25, 1939, of bronchopneumonia.
- James Persinger McNeil, Kingsport, Tenn.; Vanderbilt University School of Medicine, Nashville, 1919; aged 44; died, Dec. 24, 1939, of acute monocytic leukemia.
- Edward Ayers Johnston, Minneapolis; Hahnemann Medical College and Hospital, Chicago, 1903; aged 70; died, Dec. 30, 1939, of carcinoma of the prostate.
- Horace Clare Peabody, Sisseton, S. D.; Chicago College of Medicine and Surgery, 1916; aged 55; died, Dec. 14, 1939, in a hospital at Webster of heart disease.
- Benjamin Franklin Barnes, Elm City, N. C.; University of Maryland School of Medicine, Baltimore, 1902; aged 62; died, Dec. 31, 1939, of cerebral hemorrhage.
- John W. Little, Westerville, Ohio; Starling Medical College, Columbus, 1881; aged 80; died, Dec. 29, 1939, of chronic nephritis, arteriosclerosis and influenza.
- William S. Parks, Wapello, Iowa; State University of Iowa College of Medicine, Iowa City, 1885; aged 80; died, Dec. 10, 1939, of coronary thrombosis.
- George Nathaniel Plummer Mead, Winchester, Mass.; Harvard Medical School, Boston, 1886; aged 80; died, Dec. 14, 1939, of coronary heart disease.
- Olin Carl Diehl, Diller, Neb.; John A. Creighton Medical College, Omaha, 1902; aged 67; died, Dec. 20, 1939, of injuries received in an automobile accident.
- William F. Justus, Rushville, Ill.; College of Physicians and Surgeons, Keokuk, Iowa, 1892; county coroner; aged 71; died, Dec. 27, 1939, of myocarditis.
- Elmer Ellsworth Faulkner, Minneapolis; Hahnemann Medical College and Hospital, Chicago, 1889; aged 78; died, Dec. 4, 1939, of coronary sclerosis.
- Ramon Roca, San Jose, Calif.; Universidad de Barcelona Facultad de Medicina, Spain, 1889; aged 76; died, Nov. 12, 1939, of carcinoma of the prostate.
- Beverly Washington Hall, Mountville, Ga.; University of Georgia Medical Department, Augusta, 1891; aged 74; died, Dec. 10, 1939, of heart disease.
- Elihu Culbertson, Savannah, Ohio; University of Wooster Medical Department, Cleveland, 1880; aged 83; died, Dec. 21, 1939, of cerebral hemorrhage.
- Harry Wadsworth Slack, Corsica, Pa.; Western Pennsylvania Medical College, Pittsburgh, 1895; aged 70; died, Dec. 9, 1939, of hernia.
- Manley Blevins, Warrensville, N. C. (licensed in North Carolina in 1885); aged 80; died, Dec. 9, 1939, of perforated ulcer of the stomach.
- James Rufus Speight, Robbinsville, N. C.; Medical College of Virginia, Richmond, 1890; aged 73; died, Dec. 14, 1939, of cerebral hemorrhage.
- Benjamin Edward Robinson, Boston; Leonard Medical School, Raleigh, N. C., 1904; aged 60; died, Nov. 26, 1939, of coronary thrombosis.
- Henry Bell Pratt, Yakima, Wash.; Syracuse University College of Medicine, 1903; aged 63; died, Dec. 22, 1939, of coronary thrombosis.
- Samuel Clark Russwurm, Hughes, Ark.; Memphis (Tenn.) Hospital Medical College, 1899; aged 70; died, Dec. 21, 1939, of coronary thrombosis.
- Samuel H. Reynolds, Maplewood, Mo.; Barnes Medical College, St. Louis, 1897; aged 70; died, Dec. 15, 1939, of chronic myocarditis.
- John Aloysius Lotz, St. Louis; St. Louis University School of Medicine, 1906; aged 62; died, Dec. 26, 1939, of coronary disease.
- Colin Henry Ross, Omaha; Omaha Medical College, 1898; aged 76; died, Dec. 17, 1939, in Chattanooga, Tenn., of bronchopneumonia.
- Clark Lee Shipley, Paris, Ill.; St. Louis College of Physicians and Surgeons, 1908; aged 57; died, Dec. 24, 1939, of hemiplegia.
- Franklin P. Hulén, Wichita, Kan.; Missouri Medical College, St. Louis, 1885; aged 82; died, Dec. 20, 1939, of cardiovascular disease.
- Alvin Barnard Cary, Donnellson, Ill.; Marion-Sims College of Medicine, St. Louis, 1899; aged 63; died, Dec. 27, 1939, of heart disease.
- W. T. Green, Dayton, Tenn.; Chattanooga Medical College, 1892; aged 77; died in December 1939 of chronic myocarditis and nephritis.
- William Heitmann, Nashville, Wis.; Milwaukee Medical College, 1902; aged 64; died, Dec. 17, 1939, of cerebral hemorrhage.
- John W. Myers, Glen Dale, W. Va.; College of Physicians and Surgeons, Baltimore, 1893; aged 68; died, Dec. 19, 1939, of pneumonia.
- Samuel E. Embry, Chicago; Louisville (Ky.) Medical College, 1891; aged 82; died, Dec. 26, 1939, of fracture of the femur.
- Joseph Hoffmaster Campbell, Rutledge, Tenn. (licensed in Tennessee in 1889); aged 81; died, Dec. 9, 1939, of angina pectoris.
- Alexander G. Low, Hartwood, Va.; Chicago Homeopathic Medical College, 1899; aged 76; died, Dec. 3, 1939, of angina pectoris.
- Maskel Lee, Atlanta, Ill.; Rush Medical College, Chicago, 1888; aged 84; died, Dec. 20, 1939, of heart disease.
- J. P. Joyce, Lexington, Tenn. (licensed in Tennessee in 1889); aged 74; died, Dec. 27, 1939.

Correspondence

EFFECT OF BASIC SCIENCE LAWS

To the Editor:—The so-called basic science law was, I believe, originally intended to curb the osteopath and the chiropractor. As it operates at present, it is curbing the medical profession effectively as well. The basic science law in most states requires examination in five or six subjects. Each subject represents one year's work in that subject. It is obvious that adequate preparation for such an examination in the case of a man who has been out of school a goodly number of years is a large order. As a rule there is no reciprocity on the basic science examination, and this, together with the fact that examinations are held at comparatively long intervals, makes it an effective bar when registration is attempted.

No one will hold a location open long enough to complete a deal under these circumstances, and even for recent graduates it adds a definite degree of uncertainty. In their efforts to be fair, most boards feel that they can make no exception in favor of the medical profession, although the law was intended primarily for the nonmedical cults.

As it stands at present, it constitutes a Chinese wall for the average man who is not a recent graduate.

PAUL R. HOWARD, M.D., Oak Park, Ill.

[The letter was referred to the office of the Bureau of Legal Medicine and Legislation, which replies:]

To the Editor:—Basic science laws have never been advocated as an ideal type of legislation. They do, however, represent the most practical approach to a solution of the muddle in which medical licensure has been permitted to flounder in many of the states. A few years ago this bureau undertook to find out the views on basic science laws of state medical associations of those states in which a basic science requirement had been imposed on all applicants for licenses to practice the healing art. There was a surprising absence of complaint against such laws received from such associations. As a matter of fact, during the last fifteen years few criticisms of the principles underlying basic science laws have reached this bureau.

The burden of the grievance against basic science laws seems to be that they interfere with the customary reciprocal relations that normally exist between states in the matter of medical licensure. Generally speaking there should be no such interference. The draft of a uniform basic science act prepared by this bureau was so framed as to avoid just that result. It provides for exemption from the basic science examination of any person who submits to the basic science examining board satisfactory proof showing:

(1) that the applicant has passed in another state an examination in the basic sciences either before a board of examiners in the basic sciences or before a state board authorized to issue licenses to practice the healing art;

(2) that the requirements of that state are not less than those required by this act as a condition precedent to the issuance of a license; and

(3) that the board of examiners in the basic sciences in that state grant like exemption from examination in the basic sciences to persons holding certificates from the state board of examiners in the basic sciences of . . . or holding licenses to practice the healing art according to the method or school that the applicant proposes to follow, issued after examination by the proper license board of . . .

While there is some variance in the phraseology used in the reciprocity provisions in the several basic science acts that have been enacted, all but three (Arizona, Florida and Washington) do authorize the respective basic science examining boards to give credit to examinations passed by the applicant in the basic sciences in other states. In Arkansas, for example, the reciprocity provisions in the law follow closely the provisions incorporated in our uniform draft. While the Arkansas act does not make it mandatory that the board grant exemption from examination to licensees from other states, having proper qualifications, it does lodge with the board a discretionary right to do so. For instance, Arkansas, in 1938 115 applicants were

granted basic science certificates, of which forty-three were issued without examination or were so-called reciprocity certificates. In Iowa, as another example, 115 certificates were issued during that year, seventy without examinations. In the District of Columbia, forty-six certificates were issued during 1938, twenty-two being without examination. In all the states having a basic science law in operation during 1938, a total of 1,388 certificates were issued, 293 of which were without examination. These figures were published in *THE JOURNAL* April 29, 1939, page 1724. Corresponding figures for 1939 will be published in the State Board Number of *THE JOURNAL* for this year. During 1938, however, no reciprocity certificates were issued in four states (Arizona, Connecticut, Oklahoma and Washington). In only two of these states, however, was the failure to issue so-called reciprocity certificates due to the fact that the laws contained no provision therefor, those states being Arizona and Washington. Some difficulties have arisen in connection with the enforcement of the Arkansas basic science act, but most of these difficulties were cleared up by a recent decision of the Supreme Court of Arkansas.

There have been several instances in the past in which complaints have been voiced against basic science legislation on the ground of interference with reciprocal relations between the states. These instances have been rare and in many of them an investigation has disclosed the fact that the alleged interference was due not to any fault in the legislation itself but to administrative practices.

Dr. Howard refers to the fact that there are comparatively long intervals between examinations in basic science and that this works a hardship on applicants. In this connection, if he has in mind Arkansas, the act does not specify the dates on which examinations are to be held. It provides merely that "the board shall conduct examinations at such times and places as it deems best, having due regard to the times and places of the examinations held by the several professional examining boards authorized to issue licenses to practice the healing art in the state of Arkansas."

BUREAU OF LEGAL MEDICINE AND LEGISLATION
OF THE AMERICAN MEDICAL ASSOCIATION.

LIPOCAIC AND PANCREATIC EXTRACTS

To the Editor:—I was much interested in the article in *THE JOURNAL* January 6 by Dragstedt in which he calls attention to a substance present in the pancreas which he calls lipocaic. It might be of some aid to those interested in the subject of diabetes and disturbances of fat metabolism, as well as atherosclerosis, to know that a number of our men have been using the pancreatic extract described by Dr. Wolffe, of Philadelphia, and his co-workers, in cases of angina pectoris and diabetic gangrene, with most encouraging results. For this reason I feel that we should call to the attention of the profession that work on hormones of the pancreas, other than insulin, has been done by the Wolffe group at Temple University. There is a rich bibliography to which the Dragstedt group fails to refer.

Is Dr. Dragstedt's preparation much different from the one described by Dr. Wolffe or is it possible that he just overlooked it? In one of the recent articles, "Pancreatic Extract (Enzyme Free) in the Treatment of Diabetic and Arteriosclerotic Gangrene" (*Am. J. Surg.* 43:109 [Jan.] 1939) Dr. Wolffe says: "The active substance present in the enzyme-free pancreatic extract, which is neither histamine nor choline, exerts a beneficial influence upon lipid metabolism as well as on muscle metabolism in general. As a corollary to this, it may be that the combination of insulin, pancreatic extract and a diet low in fats will prevent the early appearance of atherosclerosis in diabetes, etc."

The same group showed that their substance, prepared in a similar fashion to that of Dragstedt, had fat influencing proper-

ties, before the International Congress in Rome in 1932, and in Leningrad in 1935. The first publication in reference to the extract appeared in the *Transactions of the American Therapeutic Society* for January 1931. Following this, one appeared in the *Annals of Internal Medicine* for November 1931. Some of the work was published in the *Archives internationales de pharmacodynamie et de therapie* 44:387 (March 15) 1933.

The Wolffe group also exhibited their work at the 1937 meeting of the New Jersey State Medical Society. An abstract of the presentation was published in 1938.

BARNEY LIHN, M.D., Vineland, N. J.

[NOTE.—This letter was referred to Dr. Dragstedt, who replies:]

To the Editor:—The papers of Dr. Wolffe have been for the most part published in obscure medical journals which it has been difficult for me to obtain. Through the courtesy of the American Medical Association Library I have secured a copy of the *Proceedings of the Fifteenth International Physiological Congress*, which was held in Leningrad in 1935 and which contains the abstract of a paper by Dr. Wolffe and his associates entitled "Desynpatone—A Fraction of Insulin-Free Pancreatic Extract." Apparently Dr. Wolffe has secured an extract from pancreas which when injected intravenously into rabbits and dogs produces a definite but transitory fall in blood pressure and which in some way seems to antagonize the pressor action of epinephrine. I have been unable to find in any of the publications of this group any evidence indicating that this extract resembles lipocain in its effect on the fatty infiltration in the liver of depancreatized dogs or on fat metabolism and transport in a general way.

It is my impression that Wolffe has been following up the work of Frey on the possible presence of what is called a circulatory hormone obtained in extracts of pancreas that are given by parenteral injection. I believe it still remains a question as to whether or not the depressor effects of such extracts are specific for the pancreas or whether they simply represent the well known depressor effects of tissue extracts in general when injected intravenously in experimental animals.

LESTER R. DRAGSTEDT, Chicago.

Professor of Surgery, University of Chicago.

To the Editor:—In 1936 I got in touch with Dr. Wolffe, after seeing the type of work he was doing with various fractions of pancreatic extract, and asked him to prepare an exhibit for the 1937 meeting of the New Jersey State Medical Society.

Dr. Wolffe and his colleagues showed conclusively that the pancreas contained hormones which differ from insulin. One they described as having an epinephrine neutralizing effect. This had previously been shown by a number of investigators, such as Frey and Kraut, Gley and Kishiniou, and Vaquez and his co-workers. Dr. Wolffe's group demonstrated modifications of the previously reported method of preparation of this particular fraction, its possible isolation and new methods for standardization. They gave due credit to the previous investigators.

In their exhibit they also showed that the pancreas contains a hormone which influences fat metabolism and which to the best of their knowledge had not been reported before. They called this substance lipolysin.

They showed that the continued administration of the epinephrine neutralizing fraction and the fat influencing fraction was a promising therapeutic agent for patients suffering from angina pectoris and intermittent claudication. They explained its actions by its power to neutralize epinephrine, to stabilize the autonomic system and by stimulating fat metabolism, thereby aiding muscle metabolism.

They reported a series of cases showing the beneficial effects obtained by the use of these two fractions in combination with

insulin in patients suffering from diabetes and atheromatosis. They urged the use of these materials from the pancreas for the relief of angina pectoris in patients suffering from diabetes, in gangrene seen in patients suffering from diabetes mellitus and in early cases of gangrene.

Dr. Wolffe and his co-workers brought with them a number of patients whom they had treated at Temple University Hospital and at the Wolffe Clinic and demonstrated the method of treatment.

I examined their exhibit very carefully and I was sufficiently impressed with the work to ask Dr. Wolffe to write a summary of the work presented. This was published in the *Journal of the New Jersey State Medical Society* in March 1938. They were also given an award for this exhibit.

In THE JOURNAL of January 6 I read Dr. Dragstedt's article with great interest. He approaches the same problem from a somewhat different point of view, but he confirms the work presented by Dr. Wolffe and his co-workers.

I am writing this letter in the spirit of fair play, as well as to point out that in reporting therapeutic advances each individual should refer to the work done by previous investigators. It would make it much easier for the general profession to follow these advances.

It is quite possible that Dragstedt and his co-workers are not acquainted with Dr. Wolffe's work, although they have quite an extensive bibliography.

ASHER YAGUDA, M.D., Newark, N. J.

SAFE TRANSPORT FOR THE UNCONSCIOUS PATIENT

To the Editor:—The missing link in the effective treatment of acute asphyxial accidents was forged a short time ago in an asphyxial emergency which took place between the state of New Jersey and the state of New York. It has heretofore been the common practice to treat the patient who has been suffocated at the site of the accident. The patient either recovers or dies "on location." This practice has been due to the fact that adequate facilities have not been available for the treatment of the patient en route from the site of the accident to the hospital. January 9 a call was received to attend a woman aged 35 residing in New Jersey who had suddenly become unconscious, whose respirations had failed and whose life was being maintained by a modified prone pressure Schafer technic. When I arrived at the site of the accident I rolled the patient over on her back and, after laryngoscopy, instituted intubation; oxygen and carbon dioxide were insufflated into the endotracheal tube under measured pressure. During the next five hours of artificial respiration by intermittent insufflation the patient was given a transfusion and the circulation was stimulated by hypodermic injections.

In the absence of a palpable radial and temporal pulse but with a regular apex beat of 100 a minute, the finger nails and ears being pink at the end of a total period of nine hours of artificial respiration, without any voluntary effort having taken place the patient was transported under endotracheal insufflation down narrow winding stairs, backed into an ambulance and, preceded by a police car, carried for a distance of some 15 miles, across the state line of New Jersey to a Manhattan medical center. She was removed from the ambulance, still under insufflation, to the hospital stretcher, taken up on the elevator and placed in the respirator under oxygen insufflation treatment. Auscultation of the heart on transfer to the respirator by the physician who had checked this observation before removal indicated that there had been no change in the circulation by reason of transportation. The patient survived approximately five hours in the respirator, the circulation finally failing and death ensuing.

Postmortem examination revealed cerebellar hemorrhage. Careful inspection of the respiratory tract revealed no evidence of trauma to the glottis or trachea and no emphysema or other evidence of air pressure in the lung tissue.

This case is believed to be of historical importance because it demonstrates the feasibility of transporting safely the patient who has ceased to breathe. Every profoundly asphyxiated patient and every patient exposed to unconsciousness and asphyxia during transportation is entitled to the benefit of the relatively simple technic demonstrated and successfully employed in this case. It is neither difficult nor costly to condition ambulances for the safe transportation of the unconscious patient.

PALUEL J. FLAGG, M.D., New York.

Director of Activities, Society for the
Prevention of Asphyxial Death, Inc.

Queries and Minor Notes

THE ANSWERS HERE PUBLISHED HAVE BEEN PREPARED BY COMPETENT AUTHORITIES. THEY DO NOT, HOWEVER, REPRESENT THE OPINIONS OF ANY OFFICIAL BODIES UNLESS SPECIFICALLY STATED IN THE REPLY. ANONYMOUS COMMUNICATIONS AND QUERIES ON POSTAL CARDS WILL NOT BE NOTICED. EVERY LETTER MUST CONTAIN THE WRITER'S NAME AND ADDRESS, BUT THESE WILL BE OMITTED ON REQUEST.

DRY NOSE AND THROAT IN FLOUR WORKER

To the Editor:—A man aged 42, employed in a flour mill, has for many years had trouble with his nose and throat, which has been variously diagnosed as sinus trouble, catarrh and irritation from flour dust. It has taken the form of dryness in the nose and throat, and he is continually trying to clear his throat. He states he feels as though there are scabs on the superior surface of his soft palate and is continually hawking, in an effort to get these scabs off his palate, and claims he does spit out large, dry, scablike pieces of dried phlegm at times. When first seen, about one and a half years ago, he seemed to have a chronic rhinitis. This has cleared up under treatment. He was treated for some time by a specialist, was given five or six roentgen treatments and has had a course of vaccine. On examination now, his nose and throat are essentially normal except for a dry, glazed appearance of the mucosa, which is most marked on the posterior pharyngeal wall. All treatment has been without success. He does seem to get some comfort from the instillation of liquid petrolatum into his nose. I suggested the use of amniotin in oil as a spray and the patient used this for about three weeks but did not continue after his first supply ran out. I also suggested that he change his employment but this he is unable to do at present. Any suggestions you might be able to make as to treatment would be appreciated. M.D., Virginia.

ANSWER.—From the description of the case it is apparent that the nasal condition is partly due to continuous irritation of the flour dust. Since this man cannot change his employment at present, it is imperative that a course of therapy be given him at the office and some procedures outlined for him at home with the view to protecting the nasal and pharyngeal mucosa, promoting nasal function and improving the general health.

Nasal irrigation with warm physiologic solution of sodium chloride, with or without sodium bicarbonate, or a simple isotonic alkaline solution will cleanse the nasal fossae adequately. If the nasal secretion or crusts have an offensive odor, a solution of potassium permanganate 2 grains to the pint of warm water may be substituted for the warm saline solution and gently irrigated into the nasal fossae. The crusts will come out in the washing leaving the entire nasal mucosa free. An application of ichthammol N. F. (10 per cent in glycerin) or one of the iodine preparations (iodine 2 Gm., potassium iodide 8 Gm., glycerin 150 cc.) to the nasal mucosa will promote the circulation of blood. It is best to follow with a bland oil spray, such as camphor, menthol and petrolatum. The stimulating solutions should be changed every now and again, to further enhance the end results.

The patient should be given instruction in the use of some suitable rubber bulb or siphon appliance so that he would be able to irrigate his nose once or twice daily without any untoward effects toward his sinuses or middle ears, and to sniff up or apply with a cotton tipped applicator a stimulating preparation along the lines of the foregoing, and follow with a spray of liquid petrolatum.

His general health should be built up to the highest possible level; the diet to consist of abundance of greens, fruits, vitamins, minerals, proteins and the like; any faults of systemic nature to be corrected and colds to be combated.

If any of the stimulating preparations are poorly tolerated or irritate unduly, they must immediately be discontinued and another substituted forthwith. Occasionally a mucosa will be found to be "sensitive" to one or more of the drugs, and because of this, it is best to abandon the use of such drugs for a time at least.

INDUSTRIAL OCCUPATION AND PREGNANCY

To the Editor:—What do you consider the best obstetric advice regarding working on the part of pregnant women, particularly in the textile industry, where there may be much reaching and pulling? Some state laws forbid pregnant women, after the fourth or fifth month, to work in any manufacturing business. Do you think it wiser to prohibit pregnant women, at any stage, to work in any industrial capacity and thus prevent the possibility of abortion and complications? Most of these women also have their own housework to do, besides working eight hours a day. Do you think this practice conducive to the good of the patient and the fetus? Isn't one purpose of modern antepartum care to warn against strenuous activity? Bernard S. Dignam, M.D., Thompsonville, Conn.

ANSWER.—No standard rules can be formulated as to the desirability of women continuing to work in industry during pregnancy. Economic factors must often carry considerable weight in any decisions in this regard. Certain general principles can be stated. Pregnant women should not continue their occupations if they are exposed to toxic hazards, particularly lead or other heavy metals. Pregnant women should not be subjected to an increased occupational hazard of infection. Occupations which subject women to excessive muscular efforts during which the intra-abdominal pressure is likely to be increased may be dangerous. Physical and mental efforts must not lead to exhaustion.

The moderate amount of physical exertion in the average occupation does not increase the hazards of pregnancy. Abortion is not increased in frequency. Normal pregnant women who have worked prior to the onset of gestation can usually continue their work until the beginning of the last trimester without harm to themselves. It is often desirable for a pregnant woman to be occupied in order to maintain a well balanced mental state.

TRAUMATIC MYDRIASIS

To the Editor:—A man was struck on the eye about one month ago by a hard object. There was no reaction at that time, with the exception of blurred vision in that eye. He came to see me one week later because of this condition. I could find nothing but a dilated pupil. This contracted with pilocarpine and his normal vision was restored. He has been under pilocarpine for three weeks because if he stops the drug for even one day the pupil dilates and, of course, his vision becomes blurred again. Would you please tell me the best procedure for a case of this type. I would also like to know the prognosis and treatment, if any. M.D., New Hampshire.

ANSWER.—Traumatic mydriasis is usually due to a slight rupture of the iris sphincter, which sometimes can be seen only with a corneal microscope. If the sphincter is ruptured, treatment is usually of no value except that a miotic can be used at any time when it is desired to contract the pupil. This would apply especially to exposure to bright sunlight. When the nerve supply to the sphincter is injured, which seems to occur occasionally, there is a tendency for the function of the pupil to become restored. Usually if restoration is to occur it will show some signs of doing this within three to six months.

FRACTURES OF NOSE

To the Editor:—What is the best first aid treatment of a fracture of the nose, either bone or cartilage? Jean S. Feldheym, M.D., San Francisco.

ANSWER.—The order of procedure is usually as follows: 1. Hemostasis. 2. Adequate cleansing of the parts. 3. Readjustment of the displaced tissues.

Hemostasis is accomplished by removing the initial clots from the nasal passages, gentle irrigation with sterile physiologic solution of sodium chloride and, if bleeding continues, the insertion of cotton plugs moistened with epinephrine. If the external parts are lacerated, bleeders should be sought for and clamped off. It is best not to use ligatures since buried catgut frequently favors secondary infection. Cleansing should be thorough by using a brush with soap and water. Foreign particles should be carefully removed. Fragments of bone which may be present in compound fractures should not be removed, since they frequently regain their vitality and therefore avoid the necessity of subsequent plastic procedures to restore the normal contour. Antitetanic serum should be given in all doubtful cases.

If seen early before much swelling has taken place the fractured bones and cartilages should be replaced immediately. This is done by combined intranasal and external manipulation. For

the former it is best to employ any smooth flat instrument such as a dull septum elevator, with which it is possible to elevate depressed or overriding fragments. (The Salinger fracture instrument has a grip handle which facilitates this maneuver.) At the same time the fingers of the other hand on the outside of the nose control the movement of the fragments and determine the resulting contour. If the nasal cartilages have been lacerated they should be accurately approximated with silk sutures placed closely enough together to prevent curling of the cut margins, which would result in a disfiguring scar. If, after reduction, the bony fragments tend to sink toward the nasal interior, they may be held in place by a light oil soaked pack wedged between the septum and nasal bones. If the nasal bridge tends to spread or deviate, it may be retained by a molded copper splint or a stent of dental modeling compound. Undue pressure must in all cases be avoided, since pressure necrosis of the skin is always a possibility.

If a case is seen at a time when swelling has already appeared to a degree which masks the deformity, repositioning of the fragments should be delayed two or three days until the application of cold compresses has reduced the swelling.

ABSORPTION OF LEAD AND ARSENIC THROUGH SKIN

To the Editor:—A man aged 25, an employee for several years of a local shoe factory, came to me in March 1933 complaining of blurring of vision. Control vision in his right eye was 0.2—1. In his left eye he counted fingers at 18 inches. On examination the eyes were completely normal externally. The fundi also were normal, except for questionable slight atrophy of the temporal half of the left disk, and perhaps slight engorgement of the retinal veins. The peripheral fields were normal but there was a large central scotoma in each eye. A diagnosis of bilateral retrolental neuritis was made. Examination of his sinuses, teeth and tonsils revealed no abnormal clinical observations. Roentgenograms of his sinuses were normal and x-ray examination of the optic foramina showed that they were of normal size. General and neurologic examinations were entirely negative. Urine and blood examinations gave normal results. Blood and spinal fluid Wassermann reactions were negative, and the Wasserman and Naguchi tests were also negative. The patient was hospitalized and given foreign protein therapy from April 10 to June 25; this was given in the form of typhoid vaccine, intravenously, beginning with a small dose and gradually working up to a final dose of 500,000,000. The patient almost always had a good febrile reaction. After one of the early injections a small hemorrhage appeared in the right eye. The injections were stopped for a time and then cautiously begun again. The hemorrhage disappeared and there were no more. During this time the patient received also potassium iodide, in increasing dosage, and vitamin B therapy. He had previously used tobacco moderately and occasional small amounts of alcoholic liquor. However, during his stay at the hospital he had none of either. There was steady improvement of vision for several weeks, so that vision in the right eye, which had decreased from 0.2—1 to 10/200, gradually improved to 0.1. Vision in the left eye improved to 7/200. However, in the first part of June vision again began to decline and definite atrophy of both disks began to be manifest. In July the patient was referred to the Wisconsin General Hospital, at which the diagnosis was also chronic bilateral retrolental neuritis. A chemical examination of the patient's blood and urine was made at the department of pharmacology and toxicology, which revealed that 19.79 Gm. of blood contained 0.024 mg. of lead, 100 Gm. of blood contained 0.121 mg. of lead, 910 cc. of urine contained 0.073 mg. of arsenic trioxide and 910 cc. of urine contained 0.027 mg. of lead. Examination of a sample of the fluid in which the patient had constantly dipped his hands while in the employ of the shoe factory revealed that it was a water emulsion of some fatty substance and contained 0.2 mg. of arsenic (expressed as As₂O₃) and 0.48 mg. of lead per hundred cubic centimeters of solution. Is it possible that the patient's retrolental neuritis could be due to lead and arsenic? Is it possible that such minute amounts in the solution he used could produce such a marked effect on his optic nerves? Should this be considered a medicolegal case and the shoe factory be made responsible for the patient's loss of vision? There were at no time any other evidences of lead poisoning.

M.D., Wisconsin.

ANSWER.—Absorption of lead and arsenic through the skin does not occur to an appreciable degree as the result of contact with aqueous solutions or suspensions of lead and arsenic compounds in the concentrations reported, and it is improbable that significant quantities would be ingested because of contaminated hands. The analytic data, obtained some months after the cessation of the occupational exposure, are unconvincing. The urinary lead concentration of 0.03 mg. per liter is well within normal limits. The urinary arsenic concentration, while somewhat higher than that of lead, is also within the upper range of normal values. The one result that suggests abnormal lead absorption was that obtained on the blood. This result is quite inconsistent with the urinary lead concentration and cannot be accepted as valid without confirmatory analyses. Large amounts of potassium iodide may induce the removal of lead from the bones and thus provide increased lead content of the blood and an increased excretion of lead by way of the kidneys. In the absence of clinical evidences of lead absorption, the result on the blood is still more questionable. One must conclude that a diagnosis of neuritis due to lead or arsenic has not been established and that, as the case has been presented, there are no grounds for placing responsibility on the employer.

SILICOSIS AND PROPHYLACTIC ALUMINUM

To the Editor:—I have been told by patients of a new silicosis "cure" presented in an exhibit at the world's fair in San Francisco last summer. I have no definite information regarding this new treatment, but it has been described as the inhalation of some aluminum compound. I would appreciate having any information concerning this treatment that you may have available.

Robert S. Smith, M.D., Boise, Idaho.

ANSWER.—At the University of Toronto, experiments dealing with silicosis have been under way for some time. The most recent experiments have dealt with the effect of aluminum dust. Experimentally it has been shown that aluminum dust in concentrations of less than 1 per cent in mixtures of silica dust will prevent the development of silicosis in experimental animals. The effects of other mineral dusts on the development of silicosis in animals has also been studied there and at other laboratories. Sufficient time has not yet elapsed for full evaluation of the merit of this mode of prevention. Certainly it cannot replace adequate medical and engineering control. There is no knowledge of its adequate trial in man; such an experiment would, of course, require many years and would be most costly.

If this procedure is of value, it is useful only in prevention; it is of no therapeutic value once the disease (silicosis) is established.

A full report of the basic work in this problem has been presented by J. J. Demy, W. D. Robson and D. A. Irwin (The Prevention of Silicosis by Metallic Aluminum: A Preliminary Report, *Canad. M. A. J.* 37:1 [July] 1937; The Prevention of Silicosis by Metallic Aluminum: II, *ibid.* 40:213 [March] 1939; The Prevention of Silicosis by Metallic Aluminum: A Study of the Effect of Metallic Aluminum—Its Mode and Permanence of Action, Effective Dosage and Methods of Administration, *Industrial Med.* 8:133 [April] 1939).

SPRUE

To the Editor:—In *Queries and Minor Notes* in *The Journal* Dec. 30, 1933, page 2445, there is an answer to a question entitled "Probable Sprue." It seems to me that the individual who answered this question has put the *Journal* on record as being out of date in the diagnosis of sprue. Taking up the specific questions seriatim: 1. The data given certainly do not substantiate a diagnosis of sprue. 2. The finding of Monilia in anything whatever to do with the diagnosis. 3. Further investigation certainly should include adequate stool examination both for bacteria and for protozoa, sigmoidoscopic examination and gastric analysis. 4. The assumption made is not borne out by the letter of inquiry, and the advice to give potassium iodide is simply nonsense. Incidentally, what is meant by the "alterative action" of potassium iodide? 5. The dextrose tolerance test is of decided importance in a case such as this and might even lead the way to diagnosis with reference to sprue. All in all, I consider the answer to the question unsatisfactory and inadequate.

Alfred C. Reed, M.D., San Francisco.

To the Editor:—In the Dec. 30, 1933, issue of *The Journal*, the reply to a query concerning a probable case of sprue seemed inadequate and also somewhat inaccurate. In the opinion of most of the recent workers in this field, the finding of Monilia in the stool of the patient is of no definite diagnostic value. The suggested use of potassium iodide as therapy has no rational basis. As aids in diagnosing the patient's condition, the following procedures would be helpful: 1. Stool fat analysis. The dietary intake of fat being known. On the usual diet the patient with sprue will have steatorrhea with a marked increase in the stool fatty acids. If the diet is low in fat, however, steatorrhea may not be found, for it is largely dependent on the dietary intake of fat (Bastell, S. H.; Keutmann, E. H.; Hyde, H. V., and Van Alstine, H. E.; *J. Clin. Investigation* 18: 121 [Jan.] 1939). 2. X-ray examination of the small intestine. In sprue this will reveal variations in caliber, pocketing, segmentation, mucosal changes and disturbances of motility (Mockie, T. T.; Miller, D. K., and Rhoads, C. P.; *Am. J. Trop. Med.* 15: 571 [Sept.] 1935). 3. Oral dextrose tolerance test. Contrary to the published report, the oral dextrose tolerance test is of importance in sprue. The dextrose tolerance curve in sprue is usually low or "flat" (Thayson, T. E.; *Non-tropical Sprue*, London, Oxford University Press, 1932; Hanes, F. P., and McBryde, Angus; Identity of Sprue and Celiac Disease, *Arch. Int. Med.* 58: 1 [July] 1936). The probable causes for the present report may be discussed in a formal report at a later date, but for the present it may be stated that the following factors seem involved: (a) Slow absorption of dextrose from the small intestine (Green, Judah; *New England J. Med.* 218: 247 [Feb. 10] 1938). (b) "Increased tolerance" for carbohydrate produced by (1) the high carbohydrate diet which is usually ingested by patients with sprue and (2) the high carbohydrate content of the stool actually absorbed by these patients. The passage of blood in the stool is unusual in sprue and warrants complete study of the lower gastrointestinal tract for other possibilities. It must be remembered that so-called symptomatic sprue as opposed to idiopathic sprue is a syndrome that may be produced by a variety of disorders of the intestinal tract. The diagnosis of the latter is made largely by exclusion. As for treatment, the best results have been obtained with large parenteral doses of relatively crude liver extracts and special diets which have been described by Miller, D. K., and Borker, W. Holsey; *Clinical Course and Treatment of Sprue*, *Arch. Int. Med.* 60: 385 [Sept.] 1937). Here again it should be stressed that in cases of some years' standing, response to treatment may be variable, slow and at times unsatisfactory.

Michael J. Lepore, M.D., New York.

Book Notices

BOOK NOTICES

Jour. A. M.
Feb. 17, 1

Industrial Dermatoses. Symposiums Presented at Meetings of American Medical Association and American Dermatological Association. Paper. Price, \$1 each; \$9 per 10 copies; \$20 per 25 copies. Pp. 174, with 5 illustrations. Chicago: American Medical Association, 1939.

The Sections on Dermatology and Syphilology both of the American Medical Association and of the American Dermatological Association have recently conducted symposiums on industrial dermatoses. This pamphlet is a convenient and valuable collection under one cover of all the papers presented, together with discussions. The symposiums were organized in such fashion as to permit orderly and logical presentation of most of the important aspects of this troublesome subject. There is remarkably little duplication of material as between the presentations in these two meetings. Under this arrangement, attention is successively directed to the need for professional education in occupational problems, to their incidence both in comparison to all cutaneous diseases and to compensable occupational diseases, to criteria for diagnosis which ought to be particularly helpful to specialists and general practitioners alike, and to practical prevention. Several papers are devoted to the relation of occupational dermatoses to workmen's compensation principles and procedure, both as general discussions and as specific problems in certain of the individual states. Separate studies concern erysipeloid, chronic granuloma and melanosis due to photosensitization as industrial problems, and there is also a timely discussion of the hazards associated with the manufacture of war gas. This collection succeeds in establishing the fundamental methods of attacking a rapidly growing and exceedingly complex medical problem. The professional status of the participants in the symposiums leaves no doubt as to the authenticity and value of their contributions.

Semelologia del midollo osseo: Studio di morfologia clinica. DI Aminta Fieschi. Prefazione di Adolfo Ferrata. VI. Biblioteca "Haematologica." Diretta da Adolfo Ferrata. Paper. Price, 70 lire. Pp. 354, with 121 illustrations. Pavia: Tipografia già Cooperativa, 1938.

In the past six years many monographs dealing with sternal puncture have been published, but in no case has the reproduction of marrow cells equalled the excellent illustrations of Fieschi's book. This point is justly emphasized in the preface by Adolfo Ferrata, the maestro of Italian hematology. The sixteen chapters cover a study of bone marrows from every type of blood dyscrasia and even include a discussion of the morphology of metastatic tumor cells. The author has attempted to carry the study of myelograms beyond the realm of percentages obtained by making differential counts and has emphasized the functional state of the marrow. He points out that there are three forces which regulate the composition of the marrow: a proliferative force, an evolutive or maturative force, and a migratory force which regulates the passage of cells into the blood stream. In order to study the proliferative force the author has made an extensive study of the frequency with which mitotic figures, aberrations and degenerations during the karyokinetic process appear. It is interesting to note that in pernicious anemia megaloblasts show a tendency toward multiple figures are not so numerous and they tend to be of a degenerative type. To study the evolutive force, Fieschi has devised a curve of maturation for the nucleated red cells and neutrophilic myelocytes which considers the numerical relations existing between the elements of the same category. The author has little faith in the leuko-erythroblastic ratio and believes that it is much more important to observe abnormal cells and those elements which are normally present in small numbers. Like most European hematologists, Fieschi has not been influenced by Doan, Cunningham and Sabin's theory of erythropoiesis and consequently describes megaloblasts in all phases of maturation as being the dominant characteristic in pernicious anemia (contrary to an abnormal maturation in this disease. The difficulties encountered when one tries to distinguish between marrows from cases of chronic infection and toxic conditions and those of leukemia are discussed. The former can generally be identified by the presence of toxic granulation and increase in plasma cells,

endothelial macrophages and histiocytes of various types. Sternal puncture in lymphatic leukemia has a greater diagnostic importance than in myelogenous leukemia. Typical cases will show 50 per cent or more lymphocytes in the marrow. But there are some cases in which the marrow does not show any leukemic change at all. This monograph contains many new ideas concerning the interpretation of bone marrow pictures. Some of the methods of study, especially those of mitotic figures, are too time consuming and detailed to be of practical value. But they, as well as the entire book, are recommended to hematologists interested in the fundamentals of marrow morphology and function.

Experimental Pharmacology and Materia Medica. By Dennis F. Jackson, Ph.D., M.D., F.I.C.A., Professor of Pharmacology, Materia Medica and Therapeutics in the University of Cincinnati College of Medicine. Cincinnati. Second edition. Cloth. Price, \$10. Pp. 906, with 81 illustrations. St. Louis: C. V. Mosby Company, 1939.

This well known and much quoted work is a source book for experimentalists. The present edition, twice as voluminous as the first, is comprehensive in experimental methods, technique and subject matter. Directions are given in detail but they are not prolix. Detail makes the difference between success and failure in an experiment. Michelangelo said "Trifles make perfection, but perfection is no trifle." Jackson has followed the gleam of Michelangelo and has shown an enormous capacity for taking pains.

The unit of procedure is the experiment. The aim is to develop a knowledge and appreciation of general pharmacologic reactions. Since there are about 400,000 known organic preparations and about as many inorganic preparations, he has used the economic principle of grouping drugs according to systemic effects. The groupings include drugs acting on the (1) central nervous system, (2) heart and circulation, (3) respiration, (4) alimentary tract, (5) kidneys and (6) involuntary nervous system. The author well recognizes that no strictly scientific or logical presentation or arrangement of such a vast number of heterogeneous substances is yet possible. He has, however, made progress in this direction.

Pharmacology is the most prominent liaison subject in medicine. Anatomists, biochemists, surgeons, internists, obstetricians, students of nutrition and practitioners of the other specialties are interested intensely in problems that involve pharmacology. The book should be of interest to each of them. It furnishes a method of procedure for almost all branches. It is impossible to summarize or evaluate the 217 animal experiments, to which the author has devoted 700 pages. Suffice it to say that if one desires to learn how to proceed in almost any field of experimental pharmacology one is likely to find it described. To guide in the work there are twenty-nine color plates on dissection and technique, and twenty-six color plates of drugs. In addition there are numerous illustrations and records to show and explain results. New drugs such as sulfanilamide, sulfapyridine, prostigmine and metrazol are included.

The experiments are arranged for economy both of animals and of time, and for comparing and showing differences in action of drugs; for example, experiment v is devised to show the action of ether, chloroform, epinephrine, acetylcholine, bromide and barium chloride on blood pressure, on respiration, on stomach contractions and on the pupil; experiment cxvii to show the action of digoxin, digitoxin, thevatin and strophanthin on blood pressure, respiration, diuresis, spleen volume and leg volume; experiment cxv to show the action of lobeline, cyanide, sodium sulfide and carbon dioxide on the carotid sinus, carotid body, aortic nerve, aortic body, blood pressure and respiration. These and many similarly arranged experiments emphasize both the pharmacology and the physiology involved in the actions.

Included in this edition is a new section on materia medica and prescription writing. A feature is the color plates of many plants, such as pilocarpus, digitalis and ergot, which yield important and useful drugs. Solubility tables, a list of words and abbreviations, a Latin-English vocabulary and an adequate index complete the volume, a work that demanded an enormous amount of laboratory work, supreme patience and perseverance. The workmanship of the book is excellent. The illustrations, descriptions and directions are definite and clear. This book will retain its place as a classic in experimental pharmacology.

The Surgery of Injury and Plastic Repair. By Samuel Fomon, Ph.D., M.D. Cloth. Price, \$15. Pp. 1409, with 925 illustrations. Baltimore: William Wood & Company, 1939.

This large book, which represents an immense amount of research, is an ambitious attempt to encompass within one volume the entire literature of traumatic surgery. The author admits falling short of the mark, as the special surgery of the neck, trunk and extremities was withheld for a future volume to supplement the present one, which deals with the structures of the exterior head. However, since almost half of the book is taken up with fundamental principles of surgical repair, it is quite evident that the most important part of the work is herein offered in complete form. The author has thoroughly analyzed the literature and presented every recognized point of view with regard to manifold aspects of traumatic surgery in general and presents them without bias so that the reader can judge for himself. The general preoperative and postoperative care of the patient, choice of anesthetics, methods of administering them, details of operating room procedure, care of shock, acid base balance and many other factors are presented thoroughly and to the last detail. Much space is devoted to the most elementary details, such as the incision, proper excision of tissue, rearrangement for suturing, types of sutures and suture material, wound dressings, tissue transplants and grafts, so that one need hardly look further for information to cover any imaginable situation. Certainly the profusion of illustrations, line and wash drawings, some with color, are in themselves a liberal education. The author evidently had in mind the average general practitioner, who usually sees the injured person first and whose initial treatment may have a great bearing on the ultimate result obtained. Yet even the experienced surgeon or the specialist in regional plastic surgery into whose hands these cases come later for the correction of traumatic defects will find much that is useful and clarifying in the abundant text. The special chapters on plastic surgery of the nose, eyelids, jaws and face, which include a considerable number of cosmetic procedures, follow the customary practice of the day and are presented simply, so that even the novice may grasp their frequently complex details. A voluminous bibliography follows each important chapter and should prove of utmost value to the student and research worker. This work of Dr. Fomon's must be seen to be appreciated, since it holds the answer to a vast number of questions that are frequently unanswered in books on general surgery. In this day and age of high speed, increasing trauma and a public that is plastic conscious, it behooves every surgeon and general practitioner to familiarize himself with the latest developments in these fields. Fomon's book should fill that need.

Epidemischer und sporadischer Ikterus: Eine statistisch-epidemiologische und klinische Untersuchung. Von Per Selander. Acta paediatrica. Vol. XXIII. Supplementum IV. Paper. Pp. 251, with 16 illustrations. Uppsala: Appelbergs Boktryckeriaktiebolag, 1939.

This monograph by Selander concerns the clinical and statistical study of epidemic and sporadic icterus. In reviewing the literature the author notes that the infective agent of icterus is unknown and that there are differences of opinion as to whether there are two distinct types of the disease or whether there is only one manifesting itself sporadically or in epidemics. In an attempt to clarify the issue the author studied 1,200 cases and reports as follows:

1. As far as onset is concerned, no difference between the two forms could be determined, although sporadic icterus occurred often in the age bracket between 2 and 7 years, while the epidemic form was more frequently seen in the 7 to 15 year group. Sex seems to have no influence on the incidence of either type of icterus.

2. In an epidemic in Gotland the reported incidence among younger patients was greater in the cities than in the country, while in the older group of children the opposite was the case. The author is unable to explain this phenomenon.

3. In both forms of the disease a time factor was evident. June and July saw a minimum and October and November a maximum of cases. This parallels the general incidence trend of contact infections as opposed to diseases, such as typhus and dysentery, which manifest themselves in alimentary disturbances.

4. The incubation time has been generally believed to average from two to four weeks in epidemic icterus. However, in examining patients convalescing from various ailments read-

mitted to the hospital because of icterus, the author found an average period of from two to three months between the initial discharge and the readmission. Most of the icterus patients had been in the hospital previously. These observations indicate a longer incubation period than is known to exist for any other acute disease, and because an epidemic could hardly flare up when the incubation period is so long there must be a form of the disease which does develop rapidly; therefore the author concludes that epidemic and sporadic icterus are separate entities, although he recommends further investigation to verify this opinion.

5. As far as symptoms are concerned, sporadic and epidemic icterus appear alike. A difference in symptoms was noted, however, between age groups. In adults the onset is more gradual and the hyperbilirubinemia reaches a maximum more slowly than in children: at the same time the icterus becomes increasingly severe according to the increasing age of the patient, it lasts longer in older persons and convalescence is slower. The sedimentation rate in children increases from the first to the second week and falls somewhat in the third. In adults the rate is higher in the second week than in the first and is still higher in the third.

6. A high icterus frequency was noted in persons with diabetes.

7. Cases of syphilis and acute yellow atrophy of the liver were also observed in the series, but the connection if any between these conditions remains unexplained.

Der Rheumatismus: Sammlung von Einzeldarstellungen aus dem Gesamtgebiet der Rheumaerkrankungen. Herausgegeben von Professor Dr. Rudolf Jürgens, Stellr. Direktor der Universitätsklinik für natürliche Heil- und Lebensweisen und Chefarzt des Augusta-Hospitals Berlin. Band XVI: Die Ischias. Von Dr. med. Hans-Georg Scholtz, dirigierender Arzt der Abteilung für Physikalische Therapie am Städt. Rudolf-Virchow-Krankenhaus Berlin. Paper. Price, 4.87 marks. Pp. 111, with 24 illustrations. Dresden & Leipzig: Theodor Steinkopf, 1939.

This monograph deals with pathology, anatomy, symptoms and therapy of "sciatica." The methods of treatment discussed include diet, antineuralgic medicines, homeopathic medicines, injections, baths, heat, contrast applications, hydrotherapy, galvanic and faradic stimulation, diathermy, roentgen therapy, radium therapy, massage, gymnastics, perineural injections, mud baths, sand baths, hyperthermia and manipulation.

A Guide to Workmen's Compensation: The Law and Its Practice in New York State. By H. D. Margulies and Max Bloom. Paper. Price, 50 cents. Pp. 96. New York: Progress Books, 1939.

On the basis of court decisions and the publications of the Labor Department of New York, the authors, both of whom are members of the New York bar, have attempted in this small paper-back booklet a comprehensive statement of the New York workmen's compensation act in popular, simple terms for the guidance of the worker, his trade union, his representative or attorney and his physician. Appended are sixteen selected rules for physicians promulgated by the state industrial commission.

Die Funktion der Nebennierenrinde. Von F. Verzar, Professor der Physiologie an der Universität Basel. Cloth. Price, 25 Swiss francs. Pp. 266, with 16 illustrations. Basel: Benno Schwabe & Co. Verlag, 1939.

This monograph contains thirty-one pages of references, which number well over a thousand. As might be expected from such a bibliography, the literature has been well reviewed. The author is to be commended for his division and organization of the material, which can best be illustrated by mentioning the chapter headings. The first forty-eight pages is devoted to the physiologic anatomy, the physiology, the preparation and the standardization of the adrenal extracts. Those compounds from the adrenal cortex isolated in crystalline form at the time of writing are discussed. The effects of the adrenal on the organism as a whole are then taken up in chapters on asthenia, carbohydrate metabolism, fat metabolism, protein metabolism, vitamins B and C, sodium metabolism, potassium metabolism, theory of cortical action, circulation after adrenalectomy, respiration after adrenalectomy, heat regulation, hypertrophy and atrophy of the adrenals, the relation between the adrenals and the other glands of internal secretion, and the relation between the adrenals and the sex glands. The final twenty pages is devoted to clinical considerations. It is obvious that the book is more valuable to the physiologist than to the physician. The author's contribu-

tion to the field has been largely in the field of absorption after adrenalectomy. He believes that cortical hormone is necessary for the absorption of fat and has published several papers in support of his views. Other investigators have been unable to repeat his experiments when the animals are kept in better condition by sodium chloride administration and have used fats less irritating to the gastrointestinal tract. It seems that more work is necessary to establish the role of the adrenals in absorption.

La fragilité osseuse congénitale (maladie de Durante). Par H. Fulconis. Préface du Professeur Laffont. Paper. Price, 28 francs. Pp. 134, with 14 illustrations. Paris: Masson & Cie, 1939.

This book on congenital fragility of bones, or osteogenesis imperfecta, is an instructive monograph on what the author calls Durante's disease. The subject is covered from various angles including the clinical and biologic. The author discusses the skeleton of the newborn, various clinical forms and the relationship of the glands of internal secretion. Evolution of the lesion is described and therapeutic deductions are given. There is a large bibliography. The monograph will interest special workers in this field.

Bureau of Legal Medicine and Legislation

MEDICOLEGAL ABSTRACTS

Medical Liens: Lien Effective Despite Compromise of Accident Case.—One of the plaintiffs was a physician who owned a hospital in Prescott, Ark. The other plaintiff was a registered nurse in the hospital. In November 1935 an employee of the defendant lumber company was severely injured in an automobile accident and was brought to the physician's hospital for treatment. The lumber company from time to time paid the medical, hospital and nursing bills until in December, when the employee filed suit against the company for damages, claiming that it had furnished him a car with defective brakes. The company then notified the physician that it would not assume financial responsibility for further services rendered the employee. Thereafter the physician and the nurse filed claims of lien under an Arkansas law which provides that a practitioner, hospital or nurse shall, on compliance with the provisions of the act, have a lien for the value of service rendered a patient for the relief or cure of an injury suffered through the fault or neglect of another, on any claim, right of action, and money to which the patient is entitled because of that injury. The law further provides that a tortfeasor who after being notified of a claim of lien pays to the injured patient anything of value as a settlement or compromise shall be liable to the lienors in an amount not in excess of the amount to which the patient was entitled from the tortfeasor.

After the claims for liens were filed, and while the suit by the employee against the lumber company was still pending, the company settled with the employee for \$4,000 without paying the claims of the physician and the nurse. Immediately on learning of the settlement and of the dismissal of the damage suit, the lienors applied to the court for an order to set aside the dismissal of the damage suit and for judgments against the company for the amounts of their claims. The trial court set aside its order of dismissal and set the case for trial. The burden of proving that the company was liable to the employee for the injuries he received was imposed on the physician and nurse, and the trial resulted in a directed verdict for the company, the court holding that the employee assumed the risk of driving the truck with defective brakes and that, since he could not have recovered from the lumber company because of that fact, the physician and nurse were without recourse against the company. The physician and nurse then appealed to the Supreme Court of Arkansas.

The company defended on the ground that it was not a tortfeasor within the meaning of the lien act, since the trial court had held that it was not liable to the employee. If the lumber company was a tortfeasor, said the Supreme Court, then the company clearly violated the provisions of the lien act because it was undisputed that it paid the employee \$4,000 in settlement

of his claim against it without having previously paid to the plaintiffs the amounts of their claims. In the opinion of the Supreme Court, the trial court misconstrued the lien act when it required the plaintiffs to assume the burden of proving a case of liability on the part of the company to the employee after a settlement had been made. If no settlement had been made and if the case had been brought to trial, then the burden of making a case would have been on the employee and if he had failed the liens of the plaintiffs would have failed also. But by compromising and paying \$4,000 to the employee, the company admitted in effect that it was in the wrong, was a tortfeasor, even though it took a release from the employee absolving it from blame.

It may be, the court said, that the employee was not legally entitled to the \$4,000 paid him, but the lumber company cannot be heard to say that he was not, because it voluntarily paid it to him in compromise of a claim of \$85,000. The lien act was enacted for the very humane purpose of encouraging physicians, hospitals and nurses to extend their services and facilities to indigent persons who suffer personal injuries through the negligence of another by providing the best security available to assure compensation for services and facilities. As the court viewed the act, it places no burden on industry nor does it tend to discourage settlements. The alleged tortfeasor may defend the action in the courts. If there is no liability on the part of the alleged tortfeasor, the lien claimant loses his claim for services. If the case is compromised, all the tortfeasor has to do is either to pay the lien claimant or get a written release of the lien claim from him.

The Supreme Court, therefore, reversed the judgment of the trial court and remanded the cause with direction to establish and enforce the lien of the plaintiffs for the amounts of their respective claims.—*Buchanan et al. v. Beirne Lumber Co. (Ark.)*, 124 S. W. (2d) 813.

Undertakers: Solicitation of Dead Bodies as Cause for Suspension of License.—The California funeral directors' and embalmers' law authorizes the board of examiners to revoke or suspend the license of a licensee who engages in the solicitation of dead human bodies, whether such solicitation occurs after death or while death is impending. Under a complaint charging a violation of this provision, the board suspended the embalmer's licenses of Drummey and Wilson and the funeral director's license of the latter. The superior court, city and county of San Francisco, issued a writ of mandate commanding the board to restore the licenses so suspended, and the case came before the Supreme Court of California for review.

The court could find nothing arbitrary or discriminatory in the provisions of the law prohibiting the direct solicitation of dead human bodies after death or while death is impending. The provision appeared to the court to be a reasonable regulation bearing a definite relation to the public health. It obviously was aimed at preventing the commercialization of death at a time when those concerned are emotionally upset and easily imposed on. The licensees further contended that the act was unconstitutional because it failed to provide for a proper notice of hearing. The act, observed the court, provides that the power to revoke or suspend a license shall be exercised "after proper hearing and notice to the licensee." It was urged, however, that the act was unconstitutional because it did not specify the form, manner, extent or duration of notice. Due process does not require, the court pointed out, any particular form of notice or method of procedure. If an act provides for reasonable notice and a reasonable opportunity to be heard, that is all that is required.

The board, in attacking the judgment of the trial court, contended that the writ of mandate is not available to a person who has been improperly deprived of a license by an administrative board to secure the restoration of that license. With this contention the Supreme Court could not agree. It has been held, the court said, that certiorari is not the proper remedy, since such boards do not and cannot exercise judicial powers, the theory being that, if the legislature attempted to confer judicial or quasi-judicial powers on statewide administrative boards, the statute would violate the California constitution, which vests the entire judicial power of the state in the courts, with certain

enumerated exceptions. The writ of prohibition likewise cannot be used to restrain administrative boards from taking action, for the reason that the office of the writ of prohibition is limited by the California constitution to the restraint of a threatened exercise of judicial power in excess of jurisdiction. In the absence of a proper statutory method of review, mandate is the only possible remedy available to those aggrieved by administrative rulings of the nature here involved. Furthermore, the court continued, since the administrative board did not exercise judicial or quasi-judicial functions, its findings based on conflicting testimony are not binding on the courts. If in the present case it should be held that the board's action in cancelling or suspending an existing license is binding on the courts, if such action is predicated on conflicting evidence, it would necessarily follow that the board exercised at least quasi-judicial powers, it being the essence of judicial action that finality is given to findings based on conflicting evidence. In addition, if an administrative board deprives a person of an existing valuable privilege without the opportunity of having the finality of such action passed on by a court of law, the due process clause of the federal constitution would probably be violated. The trial court, having power to weigh the evidence, must be conclusively presumed to have performed its duty, and its determination of the facts, based on conflicting evidence, is binding on appeal. The judgment directing the issue of the writ of mandate was therefore affirmed.—*Drumney v. State Board of Funeral Directors and Embalmers (Calif.)*, 87 P. (2d) 848.

Workmen's Compensation Acts: Silicosis an Accidental Injury, Not an Occupational Disease.—The claimant worked for the defendant lead company in its lode mine from August 1931 to April 1936, during which period he contracted silicosis for which the industrial accident board denied him compensation. He then appealed to the Supreme Court of Idaho.

One of the several issues before the court was whether or not the claimant's disability was due to an occupational disease for which no compensation was payable under the workmen's compensation act of Idaho. The evidence showed without material dispute that the rock in the mine in which the employee worked had a high silica content, that it was hard and that of the twenty-nine drills used only nine were wet drills. The wet drills were used only intermittently when the state mine inspector made his visits; when properly used the wet drills did away with the extremely dusty condition which otherwise prevailed. The result of the use of dry drills instead of the wet drills, the inadequacy of the ventilation system, the resultant exposure of the miners to silicosis and the forced condition of employment (the testimony being that when the miners complained of these conditions they were told that if they didn't like it they could quit) were all known to the lead company, the court pointed out. In addition, the company knew through its managing employees that the claimant, during his period of employment, lost weight and appetite and became short of breath and afflicted with a cough, all well known symptoms of silicosis. The authorities, the court pointed out, all agree that silicosis is in large part preventable by one device or another. The evidence in this case conclusively showed that the company, by its own experience, in its own mine, knew that by the use of wet drills the hazard could have been done away with, or at least greatly lessened. Under such circumstances the court did not believe that the claimant suffered an occupational disease within the meaning of the workmen's compensation act because an occupational disease, as viewed by the court, is one which inheres in the particular employment and cannot by reasonable means be prevented. Furthermore, the court said, the accident for which compensation is payable under the act need not occur at one instant, but there may be repetitious causes, all relatively slight, which culminate and result in as serious an injury and as frequently fatal as though the disabling or lethal blow or incident occurred at one time.

While compensation does not depend, the court pointed out, on the negligence of the employer, such negligence not only does not preclude compensation but compels it. The order of the board denying compensation to the claimant was therefore reversed and the cause remanded with instruction to award compensation.—*Brown v. St. Joseph Lead Co. (Idaho)*. 87 P. (2d) 1000.

COMING MEETINGS

- American Association of Anatomists, Louisville, Ky., Mar. 20-22. Dr. E. R. Clark, Dept. of Anatomy, Univ. of Pennsylvania School of Medicine, Philadelphia, Secretary.
- American Association of Pathologists and Bacteriologists, Pittsburgh, Mar. 21-22. Dr. Howard T. Karsner, 2085 Adelbert Rd., Cleveland, Secretary.
- American College of Physicians, Cleveland, Apr. 1-5. Mr. E. R. Loveland, 4200 Pine St., Philadelphia, Executive Secretary.
- American Orthopsychiatric Association, Boston, Feb. 22-24. Dr. Norvelle C. La Mar, 149 East 73d St., New York, Secretary.
- American Physiological Society, New Orleans, March 13-16. Dr. Philip Bard, Johns Hopkins Medical School, Baltimore, Secretary.
- American Society for Experimental Pathology, New Orleans, March 13-16. Dr. Paul R. Cannon, Dept. of Pathology, University of Chicago, Chicago, Secretary.
- American Society for Pharmacology and Experimental Therapeutics, New Orleans, March 13-16. Dr. G. Philip Grabfield, 319 Longwood Ave., Boston, Secretary.
- Federation of American Societies for Experimental Biology, New Orleans, Mar. 13-16. Dr. D. R. Hooker, 19 West Chase St., Baltimore, Secretary.
- Northern Tri-State Medical Association, Battle Creek, Mich., Apr. 9. Dr. E. Benjamin Gillette, 320 Michigan St., Toledo, Ohio, Secretary.
- Pacific Coast Surgical Association, Portland, Ore., Apr. 3-6. Dr. H. Glen Bell, University of California Hospital, San Francisco, Secretary.
- Tennessee State Medical Association, Chattanooga, Apr. 9-11. Dr. H. H. Shoulders, 706 Church St., Nashville, Secretary.

CENTRAL SOCIETY FOR CLINICAL RESEARCH

Twelfth Annual Meeting, Held in Chicago, Nov. 3 and 4, 1939

(Continued from page 522)

Heart Sounds Recorded Simultaneously with the Electrocardiogram

DRS. CLAYTON J. LUNDY and JOHN POST, Chicago: There is definite clinical value in obtaining tangible heart sound records. In 143 instances third heart sounds were recorded when they were not detected clinically. They were loudest in the presence of mitral stenosis and regurgitation with cardiac enlargement. No classification of recorded systolic murmurs was possible on the basis of the degree of heart involvement. No constant relationship was demonstrated between the type of recorded systolic murmur and severity or type of heart involvement.

A much needed dependable method of elucidation of diastolic murmurs is made available. In certain instances the loud diastolic murmur of aortic regurgitation masked the presystolic murmur of mitral stenosis on clinical examination, whereas the stethograph revealed the true facts in spite of marked tachycardia. The utility of this unprejudiced method is demonstrated further by the recording of a low pitched middiastolic murmur, which in this series of cases was not detected clinically in ten instances.

In fifty-three instances of stethographic mitral systolic murmurs, in nineteen with and in thirty-four without cardiac enlargement, there was no evidence of stenosis. In twenty-nine of these cases there were low amplitude, mixed diastolic sounds with and without clicks which could not be differentiated from breath sounds or room noise; in seven there were low amplitude and frequency sounds which diminished as middiastole was reached and increased as the succeeding first heart sound was reached; these were probably inaudible clinically and their significance remains to be explained. In twelve cases there was no reason; in five low frequency and low amplitude middiastolic murmurs occurred. Of seventy-three cases of clinical mitral stenosis and regurgitation, in forty the diagnosis was confirmed stethographically. In fourteen the condition was diagnosed on data other than a systolic murmur; in five there was a thrill without a presystolic murmur heard clinically and in nine there were short presystolic murmurs which were considered stethographically to be slapping first sounds and not true presystolic murmurs. In five cases diastolic murmurs were attributed to breath sounds and in four cases no reason could be ascribed.

A slapping first heart sound was recorded in nine instances in which the clinical diagnosis of presystolic murmur was unproved. A slapping second sound was recorded twenty-one times, in sixteen instances in the pulmonic area; this is the delayed snap (usually of the mitral valve) and was reported clinically only once.

DISCUSSION

DR. LOUIS KATZ, Chicago: The implication of the authors that an instrument for recording heart sounds is better than the clinician's ear in determining whether a murmur is present or absent is not a sound point of view. It must be determined that the heart sound recorder has the proper physical properties for adequately recording the vibrations in a manner similar to that which the average ear picks up. Most instruments exaggerate vibrations of low frequency with which they resonate, and they may not pick up the high vibration frequencies. Instrumental analysis should not replace clinical use of the special senses. These instruments perform a useful function in educating the ear but should not necessarily be used as the final court of authority. No instrument is as good as the ear of the properly trained clinician with good hearing. This is not to be interpreted as denying that clinicians vary in their experience and that some are actually tone deaf for certain sound ranges, nor does this statement deny that certain vibrations below the audible range can be recorded by such instruments in mitral stenosis. The aim in clinical practice should be to encourage and not to discourage the clinician to use his ears. This brings up the point that a sharp distinction should be made between those instruments which tend to record what the clinician can measure with his own senses and those instruments which give information not ostensibly obtainable by ordinary clinical means. The use of the latter should be encouraged; the former may not be needed for the ordinary clinical examination, however useful in research.

DR. EDWARD W. HOLLINGSWORTH, Hines, Ill.: I wonder what the authors mean by the term "unbiased." I do not believe they mean that the clinician is biased and it may refer to the fact that one obtains a mechanical graph of the sound. That depends on the accuracy of the instrument. I have used a home made instrument and am confused because the sounds are not duplicated. I think from a view of the authors' tracings that their machine acts similarly sometimes. The outstanding thing in such sound graphs is murmur and I am not sure but that a stethograph may be accurate; yet I think all such instruments are susceptible of further development and that the ear has to check the instrument and vice versa. The study of quality and timing of sounds may offer more information than the study of the murmur. This is a study which we should appreciate; it offers wide field for further work.

DR. M. J. SHAPIRO, Minneapolis: I should like to ask the authors what they mean by mitral regurgitation without cardiac enlargement. It was my impression that patients who had rheumatic fever but who did not show either cardiac enlargement or change in contour were recognized as having "potential heart disease" even though they had apical systolic murmurs. This may seem only of academic interest but for those who are carrying on a long time study in rheumatic heart disease it is necessary to be extremely careful in making the correct diagnosis in order to keep our records clear. I do not know how one makes a diagnosis of mitral regurgitation without evidence of cardiac enlargement or change in contour or both.

DR. FRANKLIN D. JOHNSTON, Ann Arbor, Mich.: This paper is timely and is indicative of the great interest relative to the graphic registration of heart sounds. Such records afford an objective check on impressions gained by auscultation, and evidence of this sort is rare in clinical medicine. I agree with Dr. Katz that care should be used in their interpretation, since the type of record that is obtained depends to a large extent on the nature of the recording system that is employed. I do not agree with Dr. Katz that the ear is always better than the graphic record. Low pitched sounds like auricular sounds or third heart sounds may be difficult for some individuals to hear and yet may be recorded without difficulty. I think that sound tracings are of great value for teaching purposes and that occasionally they are of some diagnostic worth. Concerning systolic murmurs, Dr. Bert Boone, of the United States Public Health Service, has taken sound tracings on a large group of normal children and in quite a few instances has found vibrations in systole while on careful examination no systolic murmur could be heard. I have had similar experiences occasionally, and I do not know exactly how to explain them. These vibrations are probably of no clinical significance.

DR. CLAYTON J. LUNDY, Chicago: Demonstration of murmurs in the past has been unsatisfactory, and I believe I am justified

in saying that the stethograph is here to stay. Criteria will be based on the records that are unbiased except in the technical sense indicated by Dr. Katz. Imperfections will be worked out. I believe this also answers Dr. Hollingsworth. Dr. Shapiro is undoubtedly correct about the heart association classification, but I must call attention to the insurance reports of a higher mortality rate among persons with a systolic murmur only. With that classification no consideration is given to the fact that it takes time for enlargement to take place and that the organic murmur must necessarily precede the accomplished fact of cardiac enlargement.

Effect of Distention of Abdominal Viscera on Blood Flow in Left Circumflex Coronary Artery

DRS. N. C. GILBERT, G. V. LEROY and G. K. FENN, Chicago: The opinions of physiologists differ about the nature and significance of viscerocardiac reflexes. That modifications in cardiac rhythm occur after visceral irritation is accepted and it is generally believed that such variations are instigated by the vagus nerve. The presence of coronary artery vasoconstrictor fibers in the vagus is not generally accepted. However, we have seen many suggestive clinical instances in which relief or prevention of abdominal distention has mitigated cardiac pain and nocturnal dyspnea.

Acute experiments were performed on thirteen dogs on whose left circumflex coronary artery a thermistorium of the "direct current heater" type had been installed. Subsequently the chest was closed; observations of the blood flow in that artery and of the blood pressure and pulse in a femoral artery were made. The stomachs of these animals were distended, by means of moderate air pressure in a balloon introduced through the esophagus. Distention of the abdomen was obtained by inflating the peritoneal cavity through a trocar. Some of the dogs were later atropinized and vagotomized and the experiments were repeated. The results were as follows: Distention of the stomach caused significantly decreased blood flow in the left circumflex coronary artery eleven times and increases in blood flow two times. In these experiments the blood pressure increased more often than it fell, and pulse rate changes were variable; usually a slight decrease was noted. After atropinization and/or vagotomy, the blood flow in the coronary artery increased two times, was unchanged three times and decreased once when the stomach was distended. Distention of the peritoneal cavity resulted in increased blood flow two times and decreased blood flow four times. After atropine was given, the blood flow increased with each distention. We feel that these experiments demonstrate a reflex vasoconstriction of the coronary arteries resulting from stimulation by distention of the stomach or of the abdomen generally. Similar experiments in chronically affected animals, without anesthesia, are in progress.

DISCUSSION

DR. FRED SMITH, Iowa City: The experimental observations of Dr. Gilbert and his associates pertain to an important subject. The association of gastric symptoms with anginal pain is well known, but the explanation, while suspected, has not been heretofore conclusively demonstrated. Patients presenting this picture commonly state that they are able to obtain relief by eructation of gas. I have a patient who is able to walk a considerable distance without discomfort if she takes her time. However, the least bit of effort following a meal brings on anginal pain. Moreover, the pain may come on at this time while she is at rest, and the eructation of gas gives prompt relief. This would indicate that this patient has an increase in the gastric tension which is probably associated with pylorospasm. The following points in the study just reported appear to be significant: First, the conspicuous reduction in coronary circulation in the presence of elevation of the blood pressure is important because the level of the blood pressure is the most significant single factor in maintaining the rate of the coronary flow. Second, the reported influence on the coronary circulation may be reproduced repeatedly. Finally, the effects may be abolished by the administration of atropine. These facts in my opinion justify the conclusions of the authors.

DR. LOUIS KATZ, Chicago: The authors have demonstrated that distention of the stomach and duodenum can lead to a decrease in coronary flow in the dog. It is probable that this may also occur in man, although this is not necessarily the

case. For example, it is known that epinephrine increases the coronary flow and dilates the coronary vessels in animals, and yet in man, apparently despite such an action, angina pectoris may result. Further, it does not follow that the decrease in coronary flow reported by the authors is due to coronary vasoconstriction. Other factors besides this influence coronary flow, and it is well known that reflexes will cause irregular heart action, usually in the form of extrasystoles, which can cause a decreased coronary flow. Experiments such as these cannot be taken to indicate that a reflex coronary constriction occurs by way of the vagi. Even if a coronary constriction does occur, which has not been demonstrated in these experiments, the constriction must be through the sympathetic nerves, which we have found in our laboratory are the only ones that carry coronary vasoconstrictor fibers. In the vagi only coronary vasodilator fibers were demonstrated by us, and these were of the so-called cholinergic variety, the action of which could be abolished by atropine. In short, care must be taken in interpreting changes in coronary flow as indicative of active changes in coronary caliber.

DR. W. W. HAMBURGER, Chicago: The authors of this paper no doubt know of the work of Dr. W. J. Kerr, of San Francisco, who believes that a supporting abdominal belt will prevent episodes of pain in certain patients with lax abdomens who are suffering with angina pectoris. It seems to me that Dr. Kerr's view conflicts with the conclusions reached in this report. I should like to ask how Dr. Gilbert and his associates reconcile their work with his. As a clinician, I find myself confused on whether to advise such a patient to loosen his vest or to wear a supporting belt.

DR. G. V. LE ROY, Chicago: In answer to Dr. Hamburger's question: We have wondered about the same thing ourselves. We feel that we have discharged our duty on this occasion by elucidating one mechanism and that only confusion would result if we attempted to explain every divergence that may occur. In answer to Dr. Katz, there are so many differing results reported by workers in cardiac physiology that it would be foolish to try to explain another worker's conclusions which differ so radically from our own.

The Heart in Diabetes

DR. THOMAS ZISKIN, Minneapolis: That heart complications occur in diabetes mellitus is well known. How soon heart involvement occurs and under what conditions have not been definitely proved. A study of the heart was made in a group of ninety-six veterans admitted to the hospital for the treatment of diabetes. Comparisons were made with a control group of patients with conditions other than cardiac. It was deemed significant that 46 per cent of the diabetic group showed abnormal electrocardiographic signs indicative of heart involvement and also that these abnormal signs occurred in a large percentage of the patients in whom the diabetes was first discovered on admission or had existed for one year or less.

DISCUSSION

DR. PAUL S. BARKER, Ann Arbor, Mich.: Dr. Ziskin has pointed out some features in the group which would probably be placed in the so-called adult type of diabetes. In diabetes in older people the cardiac abnormalities are common, and they are usually those of arteriosclerosis. It was of interest that changes were so common among patients whose diabetes was of approximately one year's duration; it would be of interest to reconcile this observation with the one that so many of the patients who have had diabetes for six years or longer did not show changes. The slurring as shown in some cases, I suspect, was so slight as to be of doubtful significance. Left axis deviation if pronounced can be considered definitely abnormal. Extrasystoles need not be taken as evidence of heart disease.

DR. THOMAS ZISKIN, Minneapolis: In this series the extrasystoles, although they are mentioned in the observations, were not considered of any comparative clinical value. The comparisons were made on the increase of slurring of the QRS complex and the other definite features of coronary disease. It is true that some of the slurring is very mild, but the same criterion for slurring of the QRS complex was used in the control group, and the fact that even the mild slurring was not present in the control group would indicate that this sign may be of some significance. This study brings to our attention the

fact that these electrocardiographic signs occurring early in the course of diabetes indicate that one must be on the lookout for coronary changes in the heart very early and must direct treatment accordingly.

Exercise Tolerance of Dogs After Coronary Occlusion

DRS. HOWARD BURCHELL and A. R. BARNES, Rochester, Minn.: The exercise tolerance of dogs has been studied after sudden and chronic coronary occlusion. Animals that have recovered from acute myocardial infarction have shown no decrease in ability to exercise. It has also been possible to occlude gradually the three major vessels in the dog's heart without the production of infarction and without demonstrable cardiac disability. Injection studies have shown the numerous potential anastomoses between the coronary vessels and the large anastomotic channels developing after coronary artery constriction and occlusion. Tissue grafts to the heart have not influenced the tolerance of animals for exercise.

DISCUSSION

DR. WARREN B. COOKSEY, Detroit: We have seen today two beautiful pieces of fundamental research in the problem of coronary disease. During the last few years I have had opportunity to see and be with two of my friends who have had severe cardiac infarcts. One does everything I tell him not to do, and he has shown no ill effects. I have been with the other in camp and I have been astounded at his tolerance to properly controlled exertion, though his infarction was extreme. It is, of course, common knowledge to all who see a good deal of coronary occlusion that many patients obtain a high degree of recovery. In spite of these facts and the demonstration we have just seen, one should clearly distinguish between properly controlled exertion and the more unusual or extreme forms of exertion, which can effect physiologic and pathologic changes conducive to thrombus formation. In a significant, though not large, number of cases coronary occlusion actually occurs within a few hours after an acute strain of unusual degree, a fact which must not be confused with Drs. Burchell and Barnes' experiments.

DR. LOUIS KATZ, Chicago: The method used by the authors for studying the exercise tolerance of the dog in coronary occlusion is logical. During the past week I have seen a dog in which a spontaneous infarction of the left ventricle developed, as shown by autopsy. After this the animal had discomfort and severe dyspnea, and an hour before death pulmonary edema could be demonstrated. This experience suggests that the dog, like man, shows evidence of cardiac strain in the manner postulated by the authors.

DR. A. R. BARNES, Rochester, Minn.: It is apropos in connection with this demonstration to recall some valuable work by Oberhelman and Le Count, who were studying the possibilities of demonstrating the connection between the right and left coronary arteries in both normal and diseased hearts. In many cases they found that they could carry the injection of one coronary over into the other side. In other words, those apparently normal persons have a coronary circulation that permits blood to pass from one artery to another. They believed that such a person could stand attacks of coronary thrombosis well. If they selected hearts subjected to chronic coronary disease and gave them injections, a good many would show the injection passing from one artery to the other. They believed that such a patient would probably survive and that the survival would be followed by healing with scar formation. I think the demonstration here, showing that after chronic occlusion it was possible to ligate a coronary artery with a low mortality rate but without much scar and permitting the dog to undergo normal exercise, has a real clinical bearing.

DR. FRED SMITH, Iowa City: The present study is of interest in connection with recent observations by Schelsinger, who demonstrated that even in the presence of multiple occlusion of the coronary arteries it might be possible to make a fairly complete injection of these vessels. Thus the results from the experimental study reported are comparable to what may be found in man. Therefore it would seem that the ability of an individual to withstand coronary artery disease depends on the extent of the collateral circulation and that this has a significant influence on the character and type of clinical manifestations.

DR. EDWIN F. HIRSCH, Chicago: The postmortem examination of patients who have died with coronary diseases demonstrates that the coronary artery lesions are usually in the first portions of the vessels. Beyond the constriction, the vessels are widely patent. Therefore the peripheral portions are able to dilate in the compensatory collateral circulation.

Chemistry of Atherosclerosis: Lipid and Calcium Content of Intima and Media of the Aorta With and Without Atherosclerosis

EDWIN F. HIRSCH, M.D., and SIDNEY WEINHOUSE, Ph.D., Chicago: The lipid and calcium contents of media tissues from human aortas increase with age. The increase is not correlated with the degree of intima atherosclerosis. Intima tissues without lesions have larger amounts of lipid and smaller amounts of calcium than the corresponding media tissues.

With increasing severity of the atherosclerotic lesions of the intima the proportions of free and combined cholesterol increase until the onset of necrosis; then the proportion of the combined cholesterol decreases. Also there are increased proportions of ether-insoluble phospholipids and calcium, and decreased proportions of the ether-soluble phosphatides, galactosides and fatty acids. The proportions of the individual lipid constituents in the intima and in the simple fatty deposits of the intima correspond closely with the analysis reported for these substances in blood plasma. These relations imply that the lipid deposits in the intima are the result of nonselective infiltration and precipitation of lipids from the plasma of the blood.

DISCUSSION

DR. EDWIN F. HIRSCH, Chicago: The point of view may be clarified by saying that two factors, the lipid and the tissue, are involved in this study. The earliest deposits of lipid in the aorta occur around the openings of the intercostal vessels and at other special places. Whether it is tissue structure or motion is not known, but something occurs in these places that unstabilizes the lipid material and leads to the separation of the lipid substances. The stability of the dispersed lipid material also may vary.

Relation of Arteriovenous Nicking to Enlargement of the Heart in Ambulatory Patients with Hypertension

DRS. SAMUEL A. SHELburne, J. LEEPER HAWLEY and A. S. McGEE, Dallas, Texas: We were able to show by this study of 320 ambulatory cases of hypertension that arteriovenous nicking is a late sign in this condition and that enlargement of the heart occurs at about the same time arteriovenous nicking appears, with but few exceptions. This clinical rule is so nearly constant that, if the nicking is present and the heart is enlarged, it may be assumed that the enlargement is due to hypertension, even though the blood pressure is not elevated at the time of the examination. On the other hand, if enlargement of the heart is present in a hypertensive person and arteriovenous nicking has not appeared, one may with reasonable certainty assume that there is another cause for enlargement, such as coronary, syphilitic or rheumatic heart disease. Long experience has shown that arteriovenous nicking does not occur except in hypertensive states and that it is the most reliable retinal sign of hypertension.

This study is based on a careful examination, by the senior author, of each branch of the retinal artery of both eyes in these 320 cases of hypertension, and a concomitant teleoroentgenogram, as well as a careful history and physical examination, an electrocardiogram, urinalysis and Kline tests. Of the group of patients that had arteriovenous nicking, enlargement of the heart was present in 97.3 per cent. The exceptions were studied in greater detail. In the group of hypertensive patients who had no nicking (seventy-three cases) there were four (5.4 per cent) who had enlargement, and no cause other than hypertension could be found. Two of these had questionable enlargement, as they had unusual body formations and measurement of the heart size was not reliable. We also studied heart size in relation to early arteriovenous nicking. The results were not as definite as would be expected, but they are of considerable interest. The relation of these arterial changes to glomerulonephritis has also been studied.

DISCUSSION

DR. ROY W. SCOTT, Cleveland: It has been known for many years that retinal arteriosclerosis almost always occurs in vascular disease with hypertension and that therefore an ophthalmoscopic examination affords valuable evidence from both the diagnostic and the prognostic standpoint. Appreciating the very capricious distribution of human arteriosclerosis, I question that one is justified in correlating arteriovenous nicking with cardiac enlargement as closely as Dr. Shelburne has done. The inference is made that all patients who exhibit this nicking have cardiac enlargement demonstrable by x-rays and that one does not encounter cardiac enlargement in hypertensive patients without the nicking. Such close association between heart size and retinal vascular changes is not observed in many cases of essential hypertension.

DR. LOUIS LEITER, Chicago: While the authors have collected fine clinical data, I agree with Dr. Scott that they have not drawn entirely correct conclusions. The authors were surprised to notice 35 per cent of patients with enlarged hearts who had no retinal arteriovenous nicking. It is not surprising if one remembers that, in general, it takes longer for arteriovenous nicking to develop than for cardiac enlargement. Of course if the patient has both features at the first examination it would be difficult to decide which came first without considerable additional information. It is important to attempt to correlate the eyeground changes with changes elsewhere in the body because some of the conclusions drawn from these observations may have a bearing on theories of the etiology of essential hypertension.

DR. SAMUEL A. SHELburne, Dallas, Texas: When one attempts to make clinical correlations of varying factors, one is open for criticism. If any one does not believe that when there is arteriovenous nicking there is going to be enlargement of the heart, I will not accept his opinion until he has made as careful a study as we have. It has been asked What is the practical usefulness of this work? If one knows the relation between these changes and the size of the heart, if one knows what this factor of arteriovenous nicking means in terms of enlargement and if my statement is true, then it becomes practical: If a patient has nicking and enlargement of the heart, one knows that the enlargement is due to hypertension, a sound reason for enlargement of the heart. Dr. Leiter says that enlargement of the heart occurs before arteriovenous nicking. We do not know that.

Effects of Intravenous Solutions Given to Patients With and Without Cardiovascular Defects

DRS. FARNcis D. MURPHY, JOHN GRILL and HOWARD CORRELL, Milwaukee: Our purpose in this investigation was to determine the effect of giving intravenous solutions on the cardiovascular systems of patients with and without heart disease. In determining the capacity of the cardiovascular system to make adjustments for the added fluids, the following routine procedures were employed: In addition to the usual clinical observations the venous pressure, the circulation time, the vital capacity and the blood and plasma volumes were determined. Also hematocrit studies, blood counts, the minute volume of the urine output, hemoglobin determinations and electrocardiographic studies were made. These estimations were done before fluids were administered and repeated every fifteen to thirty minutes for from six to twenty-four hours. The patients were weighed before and after the observations. A total of eighty-three patients were studied. There were fifty-three cardiac patients, of whom twenty-one belonged to grade 3, twenty to grade 2B and twelve to grade 2A according to the classification of the American Heart Association. The fluids used for investigation consisted of isotonic and hypertonic solutions. A comparison between the effects of the larger volumes and of smaller amounts was made. A correlation between the various results of the procedures employed and an interpretation of them in view of the clinical condition of the patient were attempted.

DISCUSSION

DR. WILLIAM S. MIDDLETON, Madison, Wis.: This paper is timely. Many surgeons and urologists have come to believe that they must "hydrate" their patients. It is true that the patient may need fluids under certain circumstances, but when confronted with clinical experiences of the following order one is apt to be more conservative. There is the patient who had an operation

and it was recommended that she receive 500 cc. of 5 per cent dextrose intravenously. By mistake 500 cc. of 50 per cent dextrose was given, and within a half hour's time there developed extreme dyspnea, cyanosis, pulmonary edema and engorgement of the liver. Fortunately the patient survived this harrowing experience. Another patient on whom necropsy was done in our institution had had on the recommendation of a member of the staff 11,150 cc. of fluid in two and a half hours. I do not cite this circumstance in criticism of this confrère alone but to show what can happen if physiologic principles are neglected. It is obvious that crystalloids in solution can be poured into the circulation at a speed at which the patient is unable to care for them. Obviously if one utilizes a 50 per cent solution one brings in ten times the amount of fluid administered. Whenever substances of this kind are given, one should bear in mind the relative tonicity of the solution used. The hypertonicity of intravenous infusions and the rate of their administration are the important factors in determining cardiac overstrain in this connection. (Colloidal suspensions are not included in this discussion.) In this very concrete problem the internist must consult with the surgeon for the protection of the patient.

DR. ELMER DEGOWIN, Iowa City: I have observed with increasing alarm the practice of giving large amounts of fluids intravenously. This same study can be applied to transfusions of blood as well as to injection of saline solution and dextrose. Years ago Plummer reported six instances of fatal pulmonary edema following blood transfusions in cases of heart disease. We have observed two such instances, one patient having chronic nephritis and the other subacute bacterial endocarditis. Both died within an hour after transfusion. I have seen one other striking case: 800 cc. of dextrose-blood mixture given in the jugular vein to an infant weighing $7\frac{1}{2}$ pounds (3.4 Kg.); in two hours the baby became cyanotic, and in spite of venesection he died within thirty-six hours. At necropsy the heart was dilated, the lungs were congested but not edematous and there was generalized congestion in all tissues.

Pulmonary Edema: Its Roentgenologic Appearance in Acute Glomerulonephritis Without Signs of Cardiac Failure

DRS. THORNTON SCOTT, Lexington, Ky., and RICHARD SCHATZKI and WALTER BAUER, Boston: The roentgenologic picture of pulmonary edema was described and a brief review of the literature was given. Certain features which distinguish it from that of pulmonary stasis in congestive cardiac failure were outlined. Two cases of acute glomerulonephritis with roentgenologic evidence of pulmonary edema were presented in which there was no discernible background of myocardial failure. Two other cases with definite clinical and roentgenologic signs but with less certain pathogenesis were presented for comparison. There was a discussion of recent concepts of the pathogenesis of edema of the lungs. The importance of recognition of the latent or early forms roentgenologically was stressed, that unnecessary treatment may be avoided.

Hypertension and Unilateral Renal Disease

DRS. NELSON W. BARKER and WALTERMAN WALTERS, Rochester, Minn.: Four cases were reported of unilateral chronic pyelonephritis with considerable atrophy of the affected kidney but no evidence of disease of the opposite kidney. In each of these cases hypertension had developed after the renal disease was well established. Careful studies of the blood pressure were made before and after nephrectomy, and reexaminations of the patients (sixteen months later in the first case, six months later in the second case, twelve months later in the third case and thirteen months later in the fourth case) showed that the blood pressure had returned to normal after operation and had remained within normal limits.

DISCUSSION

DR. LOUIS LEITER, Chicago: The problem presented by these cases is on the whole relatively simple, in that one is usually dealing with a unilateral renal disease in young people with normal function on the uninvolved side. Secondly, the duration of the hypertension has not been long enough to result in development of organic vascular disease in the other kidney. It seems that the renal pressor mechanism is released more easily in man than in the dog and requires much less kidney tissue to maintain

the hypertension. The exact amount of ischemic renal tissue necessary to bring about this reaction, or the quantitative aspect of the balance between the normal and the atrophic kidney, apparently varies from species to species. It should be emphasized that these relatively simple clinical cases are rare. I was pleased to hear that Dr. Barker still thinks there is such a thing as "essential" hypertension. Surgical treatment of patients, particularly in the older age groups, with active or old pyelonephritis in one kidney but with some reduction of function in the other kidney is difficult. I would urge caution in deduction as to the ultimate outcome of the operation unless the patients have been followed for a year or two after operation, especially those over 40. It is possible that in some of them hypertension will redevelop.

DR. NELSON W. BARKER, Rochester, Minn.: As Dr. Leiter indicated, it is probable that the development of hypertension in these cases depends on the amount of destruction of renal tissue. We do not have sufficient evidence to say that any localized renal lesion, no matter how small, may be responsible for the production of hypertension. It is also well to point out that, even if it is the result of unilateral renal disease, hypertension which has existed for a long period may not disappear after nephrectomy, since irreversible organic changes may have developed in the arterioles throughout the body. In a case of hypertension with one badly diseased kidney and one slightly diseased kidney, considerable clinical judgment is necessary to determine whether the bad kidney should be removed. I believe that this should depend on how bad the hypertension is and on how long it has existed. I do not think that age alone is a contraindication to surgical treatment provided the patient is otherwise in good physical condition.

A Simplified Inulin Clearance Test for Measurement of Glomerular Filtration Rate

DRS. BENJAMIN F. MILLER and ALF S. ALVING, Chicago: Our previous experiments have demonstrated that the inulin clearance at low plasma levels is an adequate measure of the glomerular filtration rate in normal, nephritic and hypertensive individuals. On the basis of these results and by employing a sensitive colorimetric method for the determination of inulin (Alving, Rubin and Miller), we have devised a simplified practical procedure whereby the glomerular filtration rate can be determined in the clinic. The measurement of the glomerular filtration rate permits one to make precise estimates of the changes that have occurred in specific functions and anatomic sections of the nephron.

DISCUSSION

DR. NORMAN M. KEITH, Rochester, Minn.: Drs. Alving and Miller have developed a new, accurate micromethod for the estimation of inulin, only a small injection of which is necessary to determine glomerular filtration rate or clearance. Their results in a small number of cases agree with results of those who have previously used inulin. I should like to remind the authors that the actual number of filtering glomeruli in chronic diffuse nephritis may not give one the true picture as to the available renal function. Oliver's reconstructions of different nephrons from chronically diseased kidneys show that there may be relatively much greater hypertrophy of the tubule than of the glomerulus; in some nephrons with enlarged tubules the glomerulus may even be absent. These anatomic facts of Oliver and functional results presented by Drs. Alving and Miller emphasize the importance of correlating function with structure. I am sure we all agree that such correlation is a major objective of clinical research.

DR. EMMET B. BAY, Chicago: I should like to ask the authors if one could use a factor of six times the inulin clearance rate to get the blood flow through the kidney in cases in which the inulin clearance is 2 per cent of normal.

DR. ALF S. ALVING, Chicago: We have not used this test in chronic pyelonephritis. I do not know whether Dr. Smith has done so, but it should be done. As regards renal flow, the normal flow is six times the glomerular filtration rate. Some workers have found that in essential hypertension the spasm of the afferent arterioles causes the filtration of a larger percentage of inulin by causing a back pressure in the glomerulus. Whether this holds for glomerulonephritis is not known.

The actual renal blood flow is perhaps a great deal higher, and we use the term "effective renal blood flow" for that reason to designate the blood flowing through actively functioning nephrons.

A Crystalline Pressor Substance, Angiotonin

IRVINE H. PAGE, M.D., and O. M. HELMER, Ph.D., Indianapolis: When renin prepared by the method of Helmer and Page (1939) is allowed to react with renin activator (Kohlstadt, Helmer and Page, 1939), a strongly pressor substance is produced which we have called "angiotonin." It is dialyzable, heat stable and alkali sensitive. Crystalline derivatives such as picrates and oxalates have been prepared. Incubation of renin with angiotonin destroys the latter; hence angiotonin is an intermediate product. It is somewhat similar to epinephrine and tyramine in its effect on blood pressure but exhibits few of their other properties. It is suggested that renin is an enzyme—not a pressor substance—which acts on a substrate (renin activator) to produce a pressor substance, angiotonin.

DISCUSSION

DR. GEORGE WAKERLIN, Chicago: Since the authors found that angiotonin increases the tone of the intestinal strip in vitro, if angiotonin is the effective pressor substance in experimental renal hypertension why is there no evidence of altered bowel motility in dogs with this type of hypertension? Moreover, if renin on intravenous injection exerts its pressor effect through producing angiotonin, as claimed by the authors, why is there no significant change in the tone or motility of the bowel when renin is injected intravenously in dogs in a dose sufficient to raise the blood pressure significantly?

DR. IRVINE H. PAGE, Indianapolis: The responses of intestinal strips in a bath may not be comparable with the responses in the intact animal. Renin itself produces no response in vitro simply because no activator is present. In answer to Dr. Wakerlin's second question, the concentrations of angiotonin used to cause contraction of the intestine in the bath are far greater than those required to produce pressor effects in the intact animal. If this reasoning is correct, much larger doses of angiotonin would be required to produce hypermotility of the intestine than to produce hypertension in the body.

Comparative Analysis of the Effects of Cold and Thyrotropic Substance on the Thyroid Gland

PAUL STARR, M.D., and RIGBY ROSKELLY, B.S., Chicago: Numerous workers have shown that there is hyperplasia in the thyroid of guinea pigs and rats which have been exposed to cold. Groups of rats were kept in an ice refrigerator under controlled conditions for three, seven, fourteen, eighteen, twenty-one, thirty-five, forty-five and fifty-six days. In all, seventy-five animals were used. The thyroid was then removed and prepared for microscopic study. The microhistometric method of Starr and Rawson was used to measure the degree of hyperplasia. Control animals living at room temperature had a mean thyroid cell height of 5.19 microns. After seven days in the cold the mean had risen to 5.97 microns, at fourteen days the mean was still only 6.10 and at twenty-one days it was 8.15 microns. After this time the cell height declined to 6.40 microns at fifty-six days. This curve thus has an early low plateau, an additional rise after fourteen days and a gradual fall, i. e. a complex concave curve. In comparison, the curve of cell height response to increasing doses of thyrotropic substance in guinea pigs shows early acceleration and gradual approach to a maximum response, i. e. a simple convex curve. This suggests different mechanisms of thyroid stimulation.

DISCUSSION

DR. ALLAN KENYON, Chicago: These observations are similar to my own of some time ago. There are big differences in response between various individuals, which may depend in part on the amount of iodine available in the diet. In my experience iodine inhibited the reaction to cold. I am looking forward to seeing what the authors will find when they use iodine and measure cell height by their exact technic. Not only did colloid accumulate under the influence of iodine in my experience but the cell height appeared to decline. This relationship is troublesome. In animals with simple goiter one

sees great cell height and a low basal metabolic rate; then after iodine has been given the basal metabolic rate may increase sharply but the cell height declines and colloid accumulates. Of course in man with intense hyperthyroidism there are usually tall thyroid epithelium and depletion of colloid, but there are many variations and the reverse may occur. It seems therefore that cell height itself is an insufficient general indicator of the amount of hormone delivered to the body. This particular experimental circumstance seems to be one of the very few in which one has reason to believe that there is increased thyroid secretion and in which the physiologic chain of events seems to be normal. Therefore it is essential to continue its careful study in the hope of finding out more about this mechanism of normal thyroid stimulation.

DR. WILLIAM S. MIDDLETON, Madison, Wis.: I wish to recall the work of Tatum on the influence of environmental temperature on the activity of thyroxine. According to most textbooks thyroxine has a period of latency of about twenty-four hours. If the rabbit is placed in an environment above the temperature of the body, the effect of thyroxine may be speeded so that within half an hour to an hour these effects may be manifested on the circulation and respiration. If, contrariwise, the animal is placed in a cold environment with the temperature below that of the body there will be a prolongation of this latent period. I believe that we all appreciate that patients with thyrotoxicosis are much better off in cold than in warm weather and, from a practical point of view, I believe the implication is clear.

DR. MOSES BARRON, Minneapolis: I should like to ask whether there was a real hyperplasia present or only a simple hypertrophy. From the lantern slides it looked to me as if there was no actual increase in the number of cells but simply a hypertrophy present. If there should be an actual increase of cells in the acini, papillary projections would develop. The histologic picture suggests an attempt at increased function which did not progress to the point of an actual hyperplasia.

DR. E. PERRY McCULLAGH, Cleveland: Any one who has had experience with bio-assay methods realizes that the ideal bio-assay is not yet at hand. The method used by the authors appears to be excellent for the assaying of thyrotropic hormone. I should like to emphasize one point with regard to the paper, namely that the degree of cell change in the thyroid is not the equivalent of hyperthyroidism. I believe that the authors do not wish to imply this, but I should like to have them express themselves definitely on this point. In this regard it may be worth pointing out that in untreated animals large thyroid glands may be seen which present a microscopic picture identical with that found in the human being in the presence of severe exophthalmic goiter, and yet the animal may have no evidence of hyperthyroidism in the ordinary sense of the word. It is clear, therefore, that the size of the cells lining the acini does not necessarily parallel the amount of hyperthyroidism present.

DR. PAUL STARR, Chicago: We have done some work on the administration of iodine after the hypertrophy has taken place with a resultant recession within ten days. I am glad to get Dr. Middleton's reminder of Tatum's work. It may be that the Tatum animals have a modified status of their own thyroid and therefore respond differently to the administration of thyroxine. With regard to Dr. Barron's question, we do not know whether there are any more cells or less, and, in response to Dr. McCullagh's remarks, we have avoided trying to make any comparisons with clinical hyperthyroidism. This method opens up the possibility of making a quantitative study of thyroid response to demand. We can study protection by nutritional factors, including iodine, vitamins, minerals, proteins and other elements of the diet, and we can study the effect of modification of the physiologic, anatomic relationships of the thyroid, as has been done by other observers. The superiority of this setup over the work recently done on cold is that we have a condition in which we are studying the response over a long period and we have an accurate means of measuring the microscopic changes. Animals thrive in this environment; in the other work they died in six or seven days.

(To be continued)

Current Medical Literature

AMERICAN

The Association library lends periodicals to members of the Association and to individual subscribers in continental United States and Canada for a period of three days. Three journals may be borrowed at a time. Periodicals are available from 1930 to date. Requests for issues of earlier date cannot be filled. Requests should be accompanied by stamps to cover postage (6 cents if one and 18 cents if three periodicals are requested). Periodicals published by the American Medical Association are not available for lending but can be supplied on purchase order. Reprints as a rule are the property of authors and can be obtained for permanent possession only from them.

Titles marked with an asterisk (*) are abstracted below.

*Asthenopia Due to Vitamin A Deficiency. F. C. Cordes and D. O. Harrington, San Francisco.—p. 1343.

Dermoid (Oil) Cyst of Orbit: Report of Case. W. E. Borley, San Francisco.—p. 1355.

Neuromyelitis Optica: Report of Case. A. G. Athens, Duluth, Minn.—p. 1360.

Tetanus and Prophylactic Use of Antitoxin Following Injuries of Eye. D. G. Cogan, Boston.—p. 1365.

Intra-Ocular Foreign Bodies: Some Comments Based on 120 Cases. E. S. Sherman, Newark, N. J.—p. 1368.

Visual Acuity Tests. S. S. Blankstein, Milwaukee, and Mary Jane Fowler, Chicago.—p. 1377.

Rhinosporidium of Conjunctiva: Case. W. B. Anderson and T. H. Byrnes, Durham, N. C.—p. 1383.

Rhinosporidiosis: Case Report. E. W. Griffey, Houston, Texas.—p. 1389.

Effect of Tartar Emetic on Course of Trachoma: Second Report. L. A. Julianelle, St. Louis; J. F. Lane, Albuquerque, N. M., and W. P. Whitted, Gallup, N. M.—p. 1390.

Vitamin D Complex in Progressive Myopia.—Knapp selected fifty-three patients because it was believed that their myopia would progress. Their age varied from 3 to 20 years. Their myopia ranged from —0.25 to —41 diopters. Vitamin D and calcium were prescribed. The dosage of the latter varied with the milk intake. For each glass of milk less than a quart two tablets of the calcium were added. Of the fifty-three patients, insufficient data were obtained on seven. Of the remaining forty-six, only twelve patients took their medication regularly. Six of these twelve showed a reduction in their myopia, two remained stationary and four progressed. Considering the forty-six patients without regard to the regularity of medication, sixteen had a reduction in their myopia, seven remained stationary, twenty-one progressed and two displayed a decrease of myopia in the left eye and a progression in the right. In other words, 66% per cent of the patients who had medication either manifested a reduction in their myopia or remained stationary. It appears to the author that a disturbance in the vitamin D calcium-phosphorus metabolism is concerned in the etiology of myopia. In the presence of a calcium imbalance there may be a weakening of the fibrous tunic, which may give rise to myopia. Once a condition of progressive myopia has been established, treatment with the vitamin D complex is indicated. The myopic eyes that respond to this therapy may undergo an actual shrinkage of the globe. For the prevention of the onset of myopia, the vitamin D complex probably has another field of usefulness. Given a patient showing a diminishing degree of hyperopia and one who is approaching the axial myopia side, it would be well to fortify his diet with vitamin D and calcium. Assuming a disorder of the vitamin D complex metabolism to be a basic factor in the etiology of myopia, the author believes that the rarity of myopia in the American Indian, the fact that the rural inhabitant is freer from this complaint than the one residing in a city, that fewer myopic eyes are found in high altitudes and the prevalence of myopia in China are readily explained. Greater food consciousness, especially in relation to vitamin supply, explains why fewer cases of progressive myopia are seen today.

Asthenopia Due to Vitamin A Deficiency.—Cordes and Harrington observed eighty-two private patients between 13 and 78 years of age with persistent asthenopia in whom, as indicated by the biophotometer, there was a deficiency in vitamin A. Treatment was instituted only after sufficient time had elapsed to obtain all possible relief from the correction of the usual causes of asthenopia. In some the symptoms were so suggestive of vitamin A deficiency that the biophotometer reading was taken at the initial examination; in the majority, however, it was obtained when the patient returned, after a month or longer, complaining of persisting symptoms. Photophobia and sensitivity to glaring lights frequently accompany avitaminosis A and 69 per cent of the patients complained of being light sensitive. Aside from this there were certain characteristic symptoms complained of consistently. Of the patients 16 per cent were conscious of the eyes and uncomfortable when using them, 11 per cent complained of headache or blurring while driving, and approximately the same number had difficulty when viewing the movies. Seven patients had marked symptoms of asthenopia to the extent that they were unable to use their eyes. In a few instances headache when using the eyes was the principal complaint. The biophotometer readings before treatment was instituted ranged between 0.7 and 4.2 millifoot candles, the average being 2.09. If Jegher's normal of 0.75 millifoot candle is accepted, the average of 2.09 is low. After treatment and before discharge the average reading had been brought up to 0.9 millifoot candle. In only 22 per cent of the cases was it possible to obtain a history of any degree of night blindness. A history of dietary deficiency was obtained in 31 per cent of the cases. For treatment carotene in oil capsules were used. In the majority of cases 30,000 units (one 10,000 unit capsule three times a day) was given daily for a period of one month and then the biophotometer reading was repeated. With this and the subjective symptoms as a guide the carotene was continued or reduced in amount until an apparent balance was obtained. If carotene is absorbed faster from the intestinal tract than the liver can convert and store it, this surplus causes a yellow color (carotenemia) to appear in the body. It is not dangerous and disappears promptly when the carotene intake is reduced. Following carotene therapy 79 per cent of the patients experienced complete relief from their symptoms, 12 per cent received partial relief and 9 per cent obtained no improvement.

Relative Cholinergic Effects of Selected Estrogens. S. R. M. Reynolds and Frances I. Foster, Brooklyn.—p. 147.

Effect of Chronic Cardiac Venous Occlusion on Coronary Arterial and Cardiac Venous Hemodynamics. J. J. Thornton and D. E. Gregg, Cleveland.—p. 179.

Studies on Increased Intracranial Pressure and Its Effects During Anoxia and Hypoglycemia. L. Yesnick and E. Gellhorn, Chicago.—p. 185.

Massive Doses of Insulin and Peripheral Blood Flow.

For determining the effect of massive doses of insulin on the peripheral circulation of seven patients with schizophrenia Abramson and his colleagues used the plethysmographic method. They state that a marked increase in blood flow was usually observed in the hand, forearm and leg at the height of the hypoglycemic response. When the hypoglycemia was terminated by the administration of carbohydrate a rapid decrease in blood flow to below the control level usually occurred, especially in the hand. When dextrose was given without the previous injection of insulin, this effect on the blood flow was not apparent.

It seems to the authors that conclusions relating to the metabolism of tissues based on changes in the chemical constituents of blood from these tissues are open to criticism, unless simultaneous blood flow studies are performed and correlated with the other data.

Effect of Phenobarbital on Mentality of Epileptic Patients.—Somerfeld-Ziskind and Ziskind think that the hazards of phenobarbital are often overemphasized. Among 600 cases of convulsive states, large doses of phenobarbital were often necessary to keep patients free from seizures, yet they never encountered an instance of serious idiosyncrasy to the drug. Mental deterioration does occur in a variable percentage of epileptic patients, and it is conceivable that chronic intoxication with drugs may be partly responsible. However, most of the pertinent statements in the literature are conjectural. The authors subjected the matter to investigation, since they could discover no controlled study as to the effect of phenobarbital on the sensorium. One hundred noninstitutionalized epileptic patients composed their series. After thorough diagnostic studies the patients were given six psychologic tests, including the Stanford-Binet test. The mean intelligence quotient was 93, seven points lower than the generally accepted average for a normal community. In the cases of cryptogenic epilepsy the average intelligence quotient was 97, but in those of the symptomatic type it was only 88. Most mental traits were normal except memory, attention and language ability, which were somewhat deficient. Tests containing primarily motor elements gave lower scores than was anticipated. The reaction time in free association tests was slower than for normal persons. Patients treated with phenobarbital showed a marked reduction in the number of spells. In all, 79 per cent of forty-eight patients given phenobarbital for a year were either free from attacks or definitely improved. The treated patients, although more severely afflicted at the outset, had only 20 per cent as many convulsions as did the controls during the trial year, and only 15 per cent as many petit mal attacks. Psychologic tests performed before and after one year of treatment with phenobarbital showed no impairment in the mentality of forty-eight epileptic patients. The control group of forty-two epileptic persons likewise did not deteriorate. Seven patients were tested before and after two years of phenobarbital therapy. On the whole, the slight changes after two years of treatment were in the direction of normality. In thirteen cases the first year was used as a control and phenobarbital was given throughout the second year. There was some improvement in performance with the psychologic tests after the year of treatment. This study indicates that phenobarbital in doses of $1\frac{1}{2}$ grains (0.1 Gm.) two or three times a day can be given for two years without resultant deterioration of the intellect.

Study of Anxiety Attacks.—Acute attacks of anxiety were the principal feature of the forty-eight cases on which Kozol based this study. The age at onset of the attacks was under 30 in thirty-three cases. In all cases circumscribed attacks were present. Forty-one of the patients spontaneously used the word "fear" in describing how they felt. In every instance the fear related to an imminent personal catastrophe of the patient himself. All but one of the patients emphasized disturbing bodily

states. More than half did not show the full picture of physical symptoms described in anxiety attacks; namely, palpitation choking, dry mouth, cold sweat, numbness of the extremities, epigastric discomfort and urge to defecate. In the majority of cases, however, the most common complaints were palpitation, choking and urge to defecate. These patients as a group lack insight into the possible relationship between the attacks of anxiety and apparently obvious situations. In scrutinizing their life situations, potentially disturbing factors appeared in all the cases. Threats of frustration of ambition were nearly as common and important as sexual factors. Personality traits characteristic of this group of patients are egotism, self centeredness, sensitivity to the opinions of others, ambitiousness, aggressiveness, intensity, apprehensiveness and anticipatory trends. In only four instances was there complete absence of personality imbalance in other members of the family. Treatment began with a search for the actual facts. When possible, practical help was given in changing the situation. Psychoanalysis was not systematically carried out in more than one case. Results of treatment were not dramatic. The attacks usually subsided while the patients were in the hospital. Twenty-eight of the patients have been followed up, one for twenty-three years. In all, improvement came with time, but few attained absolute freedom from attacks.

The Myopia Problem. A. deH. Prangen, Rochester, Minn.—p. 1083.
Effect of Anoxemia on Dark Adaptation in Vitamin A Deficiency.—By a change in certain fundamental metabolic requirements, McDonald and Adler caused the normal dark adaptation curve to become altered. They first reduced the amount of oxygen in the circulating blood and during the period of anoxemia a temporary but significant upward displacement of the intensity curve by a factor of 2.5 ($\log I = 0.4$) was observed; that is, the rod and cone thresholds were both raised by an equal amount, but the rate of adaptation was apparently unchanged. A reduced dietary intake of vitamin A caused an unequal rise in the rod and cone thresholds, the rod threshold showing the greater variation. This suggests that even though anoxemia and vitamin A deficiency both change the character of the adaptation curve, they act on different processes in the visual cycle. The rise in threshold due to anoxemia is simply additive and is the same in the normal and in the vitamin A deficiency state. This is further substantiated by the fact that vitamin A deficiency does not alter the effect produced by oxygen lack. It is known that vitamin A is concerned with the photochemical basis of the visual response, and it is probable that anoxemia acts elsewhere in the visual system, i. e. on the nerve mechanism.

Cataract After Inhalation of Paradichlorobenzene Vapor.—Berliner cites two cases of jaundice, loss of weight and cataract formation in young women following exposure to paradichlorobenzene vapor for one and two years respectively. The history in each case suggests a toxic hepatitis due to continued exposure to the fumes of this moth-repelling drug. The changes in the lenses appeared as a delayed reaction several months after the patients were removed from the influence of the fumes of this drug, a phenomenon strikingly similar to that observed in cataracts due to the toxic effects of dinitrophenol. Paradichlorobenzene inhaled in sufficient concentration caused the death of guinea pigs and rabbits and produced vacuolation

and necrosis of hepatic cells, principally in the central portion of the liver lobule. No lenticular changes appeared except in one experimental rabbit which was fed the drug orally. The public should be warned of the toxic properties of this drug, manufacturers and distributors of the product should be required to label containers properly that are sold to the general public, and the medical profession and health authorities should be apprised of the danger of prolonged inhalation of the fumes of paradichlorobenzene.

Treatment of Otitic Meningitis.—According to Cuning, attempts at treatment of otitic meningitis have been disappointing. Reports covering several thousand cases indicate mortality rates of from 95 to 98 per cent. In this paper Cuning describes the treatment and results in fourteen cases of otitic meningitis and in one case of meningitis following submucous resection. Only cases in which the pathogenic organism was actually recovered from the spinal fluid are included in this report. Treatment was similar in all cases, namely a combination of radical surgical intervention, daily spinal drainage and the intensive use of sulfanilamide or one of the related compounds. Blood transfusions and intravenous administration of dextrose were employed during the same period. In this series of fifteen consecutive cases of meningitis, eleven patients recovered and four died. Sulfanilamide, while obviously extremely important, is apparently not sufficient in itself to produce a cure. Surgical intervention in itself is not sufficient, and it seems that a combination of the two, namely sulfanilamide and surgical intervention, offers the best hope. In the use of the drug it is important that treatment be started early, that the dose be large and that the treatment be continued for several weeks after cessation of symptoms. Surgical measures likewise should be instituted as soon as the diagnosis is made. In seven of eight cases in which the invading organism was *Streptococcus haemolyticus*, recovery occurred. In two cases in which the organism was *pneumococcus* type I and one case in which the organism was *pneumococcus* type III, death occurred. Had sulfapyridine been known when the pneumococcal infections were treated, the results might have been better. Six patients showed paralysis of the external rectus muscle. It seems that with the use of sulfanilamide plus surgical intervention meningitis is not necessarily to be considered as formidable as formerly.

Gallbladder and Arthritis.—Peers studied the relation of the function of the gallbladder in seventy-one cases of chronic arthritis of unknown etiology. As revealed by the sodium tetraiodophenolphthalein test twenty-five patients had normally functioning gallbladders. On examination and questioning, ten of these patients gave no history of gastrointestinal complaints, fifteen complained of one or more of the usual symptoms of low grade indigestion and x-ray visualization of the remaining forty-six revealed stones or there was a marked variation from normal as to filling, concentration or emptying of the gallbladder. Four of the forty-six patients were reported as having gallstones and six as having no visualization of the gallbladder. Three of these six patients whose gallbladders did not react to the dye had a negative clinical history. Twelve of the remaining thirty-six patients who presented atypical observations had negative clinical histories in relation to their gastrointestinal tracts. Of the twenty-five patients reported as having normal roentgenograms twelve were considered to have arthritis of the rheumatoid type, eight osteo-arthritis and five of the mixed type. The arthritis of the forty-six patients reported with positive changes of the gallbladder was rheumatoid in thirteen, osteo-arthritis in thirteen and mixed in twenty.

Adrenal Cortex Extract for Paget's Disease.—Watson treated nine patients with Paget's disease of the bones with adrenal cortex extract. This was injected once a week into the gluteal muscles in amounts of from 5 to 10 cc. or more. In the majority of the patients there was undoubted clinical improvement, exemplified by cessation or lessening of the pain and by an increased sense of well being. Biochemical improvement occurred in all of the cases as indicated by a reduction of the serum phosphatase. In view of the favorable results which have accompanied the use of desoxycorticosterone acetate in Addison's disease, the author used this compound as a substitute for the cortical extract in some of the cases of Paget's disease. Also, a preparation of adrenal cortex designed for oral administration was tried in some instances. Injections of desoxycorticosterone acetate and the oral administration of the desiccated adrenal cortex extract did not produce as pronounced therapeutic effects in Paget's disease as did injections of the extract in solution. It is not suggested that Paget's disease

is a manifestation of adrenal insufficiency correctable by substitution therapy. Any attempt to explain the apparent salutary effect of adrenal glandular products on patients with Paget's disease would be pure speculation at the present time. That adrenal cortex extract may influence in some peculiar manner the underlying metabolic derangement in Paget's disease is suggested by the fact that a patient with cystic fibrous osteitis and an associated hyperphosphatasemia was treated with adrenal cortex extract without any reduction of the serum phosphatase or relief of pain. The fact that the synthetic cortical hormone, desoxycorticosterone acetate, did not seem to be as efficient in lowering the serum phosphatase or relieving the symptoms of patients with Paget's disease suggests that something in the cortical extract other than the hormone was responsible for the results. Williams has shown that adrenal cortex extract does not inactivate or inhibit bone phosphatase in vitro. Therefore it must be assumed that the therapeutic effects cannot be explained on the basis of inactivation or inhibition of the enzyme in the blood stream by the extract following its injection, but rather that a modifying influence is exerted on the tissue cells. Pending the acquisition of further scientific data the employment of adrenal glandular preparations in Paget's disease, although encouraging, must remain at best an empirical form of treatment.

Treatment of Hemangiomas with Solid Carbon Dioxide.—At the Hospital for Sick Children, 156 children with hemangiomas of various types were seen in the skin clinic during 1934 and 1935. In the spring of 1937 Wrong asked these patients to report for observation and seventy-eight did so. Of the seventy-eight patients fifteen had more than one lesion and the largest number of lesions treated with solid carbon dioxide on any one child was four. Of the ninety-six hemangiomas treated the results were excellent in thirty-seven, good in twenty-three, fair in sixteen and poor in twenty. Most of the good results were obtained in the tumors which were less than 1 cm. in diameter. When the tumor was between 1 and 2 cm. there were as many indifferent results as good ones. When the size reached more than 2 cm. the good results were few. A complicating factor to consider is that most of the larger lesions were also deep. The depth of the tumor is an important factor in determining whether a tumor will respond to freezing by solid carbon dioxide or not. The results in the thin lesions were nearly all excellent or good. In the thicker lesions this condition was somewhat reversed, and in the thick and pulpy lesions, i. e. those with subcutaneous involvement, there were no good results.

Dextrose Tolerance Tests.—Among 51,096 routine urine examinations of students (average age 22.7 years) Watson found glycosuria to occur 583 times, or in 1.14 per cent of the cases. Of 33,125 urine examinations of male students glycosuria occurred 368 times, or in approximately 1.11 per cent, while among 17,971 such examinations of female students glycosuria was found 215 times, or in 1.19 per cent. In determining the incidence of glycosuria during tolerance test and its effect on mean blood sugars 186 of the 368 men and fifty-seven of the

215 women had glycosuria on one or more occasions during the test. Why almost twice as many men as women showed glycosuria is difficult to explain, as all subjects were given 100 Gm. of dextrose and the test was carried out under the same conditions in the two sexes. Of the 583 persons studied, ninety (15.4 per cent) had evidence of a definitely disturbed dextrose tolerance. Only forty-nine of the 583 subjects had a previous history of glycosuria and thirty-three of these forty-nine subjects had glycosuria sometime during the tolerance test. All blood sugar values of these subjects were slightly elevated except that of the fasting specimen. Some of these individuals might have had a mildly disturbed carbohydrate metabolism when glycosuria was first found, but because another urine specimen may have shown no sugar they were not treated at the time. Thus, during the elapsed time between the first and the second diagnosis of glycosuria one might expect a further loss of carbohydrate tolerance. A study of the relation of weight to the tolerance test revealed that the underweight (less than 90 per cent of normal) and normal weight subjects of both sexes had higher blood sugar values than the overweight (more than 10 per cent over normal weight) group. Of the 583 students with glycosuria, 67.7 per cent were of normal weight, 16.1 per cent were underweight and 16.1 per cent were overweight. This appears to be a normal weight distribution among the general college population. From the data obtained the author asserts that it is impossible to demonstrate that obesity by itself plays any part in the causation of a disturbed dextrose tolerance test. In fact, he believes that on a basis of his observations one would predict that underweight persons would be more likely candidates for disturbed carbohydrate metabolism than those who are overweight. Thus one may conclude that in this age group obesity plays no important part in the etiology of a disturbed carbohydrate metabolism. Among 109 students with a family history of diabetes the incidence of disturbed dextrose tolerance tests was 17.4 per cent as compared with 14.9 per cent among the remaining 474 students with glycosuria but with no family history of diabetes. Thus heredity cannot be considered an important etiologic factor in the production of a disturbed carbohydrate metabolism in this age group.

Fatigue of Neurotic Patients and Adrenal Cortex.—Huddleson and McFarland gave orally glycerinated adrenal cortex (pills) to fourteen patients suffering from psychoneuroses marked by asthenia. The experimental period for each patient was from ten to fifteen weeks. One week no medication was given, followed by two weeks of placebos. These three weeks, and occasionally later on placebos were given for a week, served as controls. The increasing doses of adrenal cortex pills ranged from fifteen to forty-eight pills daily, each pill representing 3 grains (0.2 Gm.) of fresh gland. Half the patients reported subjective improvement. Half gained a kilogram (2½ pounds) in weight. The basal metabolism weight was accelerated (improved) in eight. The Schneider index was bettered in nine and unaffected in five. The inventories of psychologic and of physiologic complaints showed improvement, respectively, in seven and six of the ten patients so tested. The word association test indicated fewer neurotic responses in seven, neuromuscular coordination was improved in five and perseveration was lessened in four. Following the medication, objective tests showed improvement of more than half of the patients. Seemingly this treatment has proved valuable in obstinate asthenic psychoneurosis.

Changes Induced in Senile Vagina by Estrogen.—According to Finkler and Antopol, of thirty-seven patients presenting symptoms of senile vulvovaginitis twenty-one were treated by local application of estrogenic ointment and sixteen were given estrogenic substances orally. Topical application, especially to patients who had only slight or no general menopausal symptoms, alleviated the symptoms of senile vulvovaginitis and produced pronounced histologic changes in the vagina. Patients presenting inflammatory changes superimposed on an atrophic vaginal mucosa responded rapidly to local treatment. Evidence that systemic absorption takes place in the course of inunction was manifested by slight to moderate improvement in the vasomotor symptoms of the menopause and a recurrence of uterine bleeding in one case. Oral administration of estrogens also proved of value. The results were similarly beneficial. This

form of therapy is indicated in patients presenting marked vasomotor disturbances in addition to the symptoms of senile vulvovaginitis. In many instances oral medication was substituted for intramuscular medication, because of the reappearance of uterine bleeding after injection treatment. Uterine bleeding, however, occurred in the two patients treated orally with diethylstilbestrol. This would seem to indicate unusual oral activity of the substance. Such bleeding did not occur in patients receiving two other estrogenic preparations. Of the twenty-one patients treated by inunction, six obtained partial relief and fifteen showed marked improvement. Of the sixteen patients treated orally, only one failed to respond. Better cooperation on the part of the patient was obtained when the treatment was given orally.

Stuttering as Emotional and Personality Disorder.—Solomon believes that stuttering is a specifically conditioned personality, emotive behavior and speech disorder in the struggle for equilibrium during social converse. It is a type of adjustive behavior. As stuttering is an overactive response of the total personality, there are responses at all levels of activity, depending on the stage of maturation of the individual. The objective phenomena are present in varying degree and quality in the first and recurrent moments of stuttering. They include: (1) activities in the peripheral speech machinery; disruption of coordination of the oral, laryngeal and respiratory systems, with terminal speech block, either clonic and incomplete as in hesitation and repetition or tonic and complete as in failure to produce any sound, (2) skeletal manifestations, with postural, gestural reactions from head to toes, (3) visceral and autonomic responses, from tachycardia to secretory and excretory changes and (4) physiochemical upheaval, peripheral and central, including electroencephalographic manifestations. The subjective, so-called mental, phenomena occur in the first moment of stuttering, when there seems to be mainly a state of excitement (which may be preceded or followed by other emotions). With recurrent moments the final product is very complex. Generalized expectancy occurs whenever the stutterer confronts a conditioned social speech situation and is often accompanied by a search for speech difficulty and a rehearsal of planned verbal expression. Specific expectancy occurs when he attempts a specific

word. This gives rise to various expectant devices, such as avoidance, giving up the speech attempt, substituting a different word; postponement, pausing, repeating preceding words; initiation or using "starter" words; antiexpectancy and disguise, a monotone, singsong speech, and preparatory set for release reaction. Stuttering is a clinical syndrome. Careful consideration of all internal and external factors responsible for its onset and continuation is essential (physical condition, the routine daily program and habits, the personality makeup and problems, the living conditions and personalities in the home, neighborhood, school and workshop). Treatment should include the total personality and not only the speech phenomena. It should be a combination of physical and mental hygiene, physical therapy, psychotherapy and environmental therapy adapted to the particular patient, with the goal of readjustment. Especially valuable is intensive personality study and reorganization leading to better peace of mind and social adjustment. Stuttering can be properly understood only by the application of basic scientific principles.

Psychoses with Pernicious Anemia.—From 1931 to 1938, Wiltrakis and Partipilo encountered twenty-four cases of pernicious anemia among the 13,023 mental patients admitted to the Elgin State Hospital. The diagnosis of nine, in addition to the anemia, was psychosis, of seven paranoid symptom complexes, three were classified psychosis with cerebral arteriosclerosis and the others had various mental diagnoses. The pernicious anemia was considered the primary cause of the psychosis of sixteen of the twenty-four cases. In twelve the anemia was observed prior to the onset of mental symptoms and in the remaining four within a maximal period of one year after the onset of psychosis. The psychosis of pernicious anemia is not characterized by any specific form of mental behavior, yet certain mental symptoms predominate. A marked irritability is frequently present and paranoid states, confused states and depressions are observed often. Undoubtedly the prepsychotic personality is of considerable importance in the reaction pattern. Prominent among these symptoms are marked irritability and uncooperativeness. The adjectives frequently used in literature in describing the behavior of these patients are irritable, stubborn, peevish, surly, obstinate, disagreeable, faultfinding, cantankerous and refractory. A pronounced symptom of nine of the sixteen patients was irritability. Prognosis in this psychosis is poor, yet mental recoveries do occur and the patients should be given the benefit of prolonged and extensive antianemia therapy.

Vitallium for Fixation of Fractures.—Because of the many disastrous results observed, Campbell formerly avoided the use of metal plates for the fixation of fractures, but after the introduction of vitallium he began to use it for selected cases. Since February 1937 he has employed this material in 108 cases. Roentgenograms made over a period of several months have shown no evidence of absorption of the bone about the screws or of inflammatory changes in the soft tissues. Callus appears to have covered the plate partially in many of the cases. Eight plates have been removed at periods varying from four to ten months after operation. In every case the screws were firmly embedded in the bone, necessitating removal with a screw driver. There was no evidence of corrosion or tarnishing of the metal, nor was the soft tissue about the plates stained; rather, it appeared to be normal scar and fibrous tissue such as is found in the healing of any surgical wound. Accurate alignment of the fragments was maintained in all fractures with the exception of one. A review of a large number of fractures from which wires, pins and screws of ferrous materials, Parham bands and steel plates of the Lane type were removed shows that ferrous materials often induce an unfavorable tissue reaction about the fracture site; yet obviously inefficient mechanical fixation is a

definite factor in producing complications requiring removal of the material. Laxity in the practice of strict asepsis also contributes to a not inconsiderable number of disastrous results following open reduction and internal fixation. Exposure converts a simple fracture into a compound fracture, with many of its risks. However, with proper observance of asepsis and accurate fixation by vitallium the dangers of open reduction and internal fixation are minimized and are outweighed by the advantages of replacement and maintenance of the fragments in anatomic position.

Sulfanilamide and Experimental Tuberculosis.—Follis and Rich observed the effect of sulfanilamide on experimental tuberculosis in the rabbit, and the results confirm their previous study on the guinea pig which demonstrated that adequate doses of the drug, properly administered, have a definite inhibitory effect on the development of the disease. Individual rabbits exhibit marked differences in the degree to which they acetylate the drug and in their ability to attain and maintain a high concentration of the drug in the blood following the administration of a given dose. These differences undoubtedly play a part in determining the degree to which a given dose of the drug will exert a beneficial effect on the progress of the tuberculosis in different animals. No conclusions regarding the effect of sulfanilamide on human tuberculosis should be drawn from the experiments, as that requires a separate and carefully controlled study.

*Factors Influencing Survival of Spirochetes in Frozen State. T. B. Turner and Nancy L. Brayton, Baltimore.—p. 639.

Virulence of Spirochetes and Filtrable Viruses in Frozen State.—Turner and Fleming tested the virulence of five specimens of *Spirochaeta pallida* belonging to four different strains and seven specimens of *Treponema pertuense* belonging to five different strains after storage for approximately three years at a temperature of -78°C . With one exception each specimen contained actively motile spirochetes and all specimens were highly pathogenic for rabbits. Many other specimens of these spirochetes stored for shorter periods were also tested with similar results. Relapsing fever spirochetes tested after storage for from six months to one year showed active motility and were virulent for mice. *Leptospira icterohaemorrhagiae* was found to be actively motile after storage for five, six and ten months. The spirochete of rat bite fever, *Spirillum minus*, was virulent for mice after storage for one year. The virus of human influenza, PR8 strain, tested after storage for approximately three years was fatal to mice in essentially the same dilution as was the same lot of material before freezing. Similar results were obtained on testing the virus of meningopneumonitis after storage for three years. The virus of venereal lymphogranuloma was pathogenic for mice after storage for ten months.

Factors Influencing Survival of Frozen Spirochetes.—From a study of factors which influence the survival of spirochetes in the frozen state, Turner and Brayton conclude that the optimal conditions for the preservation of spirochetes, and probably other micro-organisms, in the frozen state are afforded by rapid cooling, storage at -78°C . and rapid thawing. These organisms are severely damaged by storage at temperatures of -20°C . or higher and by slow thawing.

Complement Fixation Test in Psittacosis.—Meyer and Eddie discuss three importations of psittacine birds. Preliminary studies indicate that with the complement fixation test it may be possible to separate infected or recovered birds from healthy ones. Two of six serums collected from laboratory workers and bird inspectors gave repeatedly specific fixation reactions in dilutions of 1:8 to 1:16. These two workers, who have been intimately exposed to virus, have never had any illness suggestive of psittacosis except the usual colds. Subclinical silent infections have always been suspected. A man and wife permitted a sick bird to pick seeds from their lips. His blood serum gave a gradually increasing specific complement fixation reaction in the presence of psittacosis antigens (1:32). Her blood serum reacted in a dilution of 1:8 and rose within twenty days to 1:16. The exposure probably led in the man to a clinical and in the wife to a subclinical infection. A laboratory worker who contracted psittacosis and was desperately ill on the sixteenth day was given, both intravenously and intramuscularly, 125 cc. of convalescent serum with a neutralization index of less than 4.0. Within twenty-four hours his temperature dropped. The extensive pneumonic process began to clear four days after the administration of the serum. If any benefit is to be expected, it is important to use serum high in neutralizing antibodies. Hyperimmune serum prepared on goats is now available from the Hooper Foundation. The authors' conclusions are that: The complement fixation tests with cocto-antigens prepared from virulent mouse spleens or preferably Rivers-Li tissue cultures of the virus are invaluable aids in the early and late diagnosis of human psittacosis. Convalescent serum may shorten the course of the disease and should be tried. Highly potent goat serum may be equally effective.

Histaminase for Urticaria.—Laymon and Cumming used histaminase in treating seventeen cases of urticaria, two of urticaria factitia and eight of atopic dermatitis. These cases had proved refractory to all other types of treatment. In the cases in which histaminase was administered, no other treatment was given. In most instances histaminase was given by intramuscular

cular injections from one to three times a week as well as two or three tablets three times a day by mouth. There were no unfavorable reactions to the drug. Ten cases of urticaria were clinically cured. The duration of treatment varied from four days to three weeks. The average time for cure was 10.7 days. Two patients improved. One patient had urticaria for nine months and was 50 per cent improved after three weeks of treatment. Another patient had urticaria for several years and was 90 per cent improved after two months of treatment. The duration of the urticaria in the five cases in which improvement did not occur was from several weeks to three and a half years. There was no improvement in the two cases of autographism. No definite improvement was experienced in any of the cases of atopic dermatitis, although one month's trial of histaminase was given. From the results in their few cases the authors feel that histaminase is a useful adjunct to other therapeutic measures in urticaria. The nature of whatever antiallergic properties histaminase possesses are as yet not known. It may be that histamine is inactivated.

Infectivity of Saliva in Early Syphilis.—Saliva obtained directly from the parotid duct of seven patients with florid secondary syphilis was inoculated by Barnett and Kulchar into rabbits. The results were negative. The infectivity of saliva in patients with syphilis probably is due to contamination from intra-oral syphilitic lesions.

Prostatic Obstruction.—A review of the results of 200 consecutive transurethral resections and 234 prostatectomies, Abeshouse states, shows that transurethral resection is the preferred operation for cases of median bar, solitary median lobe and solitary subcervical hypertrophies. It affords palliative relief for persistent suprapubic fistulas and for cases of carcinoma with obstructive symptoms and provides an excellent method of removing obstruction caused by contractions, nodules or tags following prostatectomy. The operation is not suitable in cases in which there are large bilobe or trilobe hypertrophies with marked intravesical or intra-urethral bulging. He finds that suprapubic prostatectomy is suitable for cases with marked enlargement of the prostate, especially for those accompanied by conditions of the bladder requiring operative treatment. Perineal prostatectomy is an ideal operation for treating large hypertrophies and small fibrotic glands with or without prostatic calculi. It is the only method offering a cure for early or concealed carcinoma. It requires greater operative skill and, when properly done, gives an equally good functional result. Mastery of the operative technic will dispel the fear of incontinence, impotence and fecal fistula. The most important lesson derived by the author from this study is that every patient with prostatic obstruction, irrespective of age, risk or type of obstruction, can be offered a reasonable hope of relief or even cure by the judicious selection of the proper type of operative procedure.

Acute Leukemia and Erythremia.—The virus theory of the leukemias, according to Gerundo, should receive more attention. There are enough observations to establish the hypothesis on solid ground. From a comparative study between tumors and leukemia it is evident that leukemias are not tumors nor similar to tumors in any way, since they are systemic diseases of tissue present in every part of the body. The atypical cells of cancer are never found in leukemia. The fact that cells show mitoses does not prove their malignant condition, since mitoses are always present in normal bone marrow. The mitoses are never atypical in leukemia, while they are almost always atypical in cancer. The leukemic infiltrations are not present where there is no potential hemopoietic tissue, as in the brain, and leukemic growths have not been found inside the nervous tissue. The author agrees with the conception of Ferrata and many other hematologists of a hyperplastic process of the hemopoietic organs. Such hyperplasia may be brought about by the action of a virus. A new conception is advanced to explain the phenomenon of leukopenia. The normal functional inhibition of the spleen on the growth and expulsion of the cells from the bone marrow and hemohistioblastic nests may be increased, producing a leukopenic state, and may suffer oscillations in capacity or rate, offering periods of complete aleukemia alternating with periods of marked leukocytosis.

*Intracranial Complications in 250 Cases of Surgical Mastoid Infections. A. L. Juers, Louisville.—p. 585.

Intracranial Complications of Surgical Mastoid Infections.—In 250 cases of surgical mastoiditis Juers encountered seventeen instances of intracranial complications (eight of petrositis, two of labyrinthitis, one of meningitis and six cerebral abscesses). He observed that the development in not a few of the intracranial complications could have been prevented if the patient had sought and been given earlier treatment for a potentially dangerous otic infection. As these cases were all seen before the era of sulfanilamide and its derivatives their management would at present be somewhat different, and more conservative surgical procedures could probably have been carried out in some of them. However, delay in the adequate surgical treatment of long-standing suppurative otitis media is still responsible for a large number of intracranial complications. While this is only too well known to otologists, some physicians and most laymen still regard a painless draining ear as a condition of no consequence. In addition to complete exenteration of all accessible mastoid cell structure, wide uncovering or decompression of the dura over a suspected intradural lesion rules out the presence of any extradural

pathologic change or it discloses a lead of infection through the dura or it allows room for swelling incidental to inflammation of the brain tissue, whether it is a localized meningitis or encephalitis or an abortive or a cerebral abscess. In the latter instance the decompression may enable the patient to survive until it is felt that the abscess is sufficiently walled off to permit surgical drainage through a clean area later. When relief of increased intracranial pressure is urgent, ventricular puncture should be considered. In the presence of an abscess, however, its use is attended by some danger. The author believes that intracranial complications would not have developed in five of the six fatal instances if earlier adequate surgical treatment had been given.

Barbituric Acid and Mental Health.—Robinson states that barbituric acid compounds do not promote but delay recovery from mental ill health. They further impair an already impaired brain nutrition. Sugar is the chief food of the brain for its activity. At the Neurological Hospital, where tolerance tests are done as a routine, in practically 100 per cent of all cases of psychoses, neuroses and alcoholic and narcotic addiction there is found an abnormally low ability to metabolize sugar. He suggests that insulin may be the answer, as it promotes sugar metabolism and if wisely administered, is an excellent sedative and hypnotic, and when given with dextrose it corrects states of disordered brain nutrition and disordered brain function. In the treatment of mental ill health barbituric acid compounds have a place, but only to meet emergencies and to relieve the patient temporarily of insomnia and mental distress.

Synthetic Vitamin K₁ in Hypoprothrombinemia.—Frank and his collaborators used synthetic vitamin K₁ (2-methyl-3-phytyl-1,4-naphthoquinone) for the first time in two cases of obstructive jaundice. Before reporting the histories of these cases they say that no ill effect was observed in white mice, which were fed 10 mg. doses of the synthetic vitamin, nor in three human subjects each of whom was given 20 mg., together with bile, by mouth. For intravenous use the synthetic vitamin, which is an oil at room temperature, was given as a

freshly prepared colloidal suspension in 10 per cent dextrose. This solution was prepared by dissolving 10 mg. of the oil in 2 or 3 cc. of absolute alcohol; this was boiled in order to sterilize the quinone and was slowly introduced, by means of a pipet, below the surface of a well agitated sterile solution of 1,000 cc. of 10 per cent dextrose in distilled water. The final solution was slightly opalescent. No particulate matter could be seen microscopically nor was there any tendency for the quinone to separate as an oil, even after standing for several days. The case histories are accompanied by charts recording the responses in terms of drops in prothrombin clotting time following oral and intravenous administration of synthetic vitamin K₁. In the first case a single dose of 10 mg. of synthetic vitamin K₁ given by mouth with bile on two occasions to a patient with an elevated prothrombin clotting time produced a drop which was maximal at the end of twenty-four hours. The time rose again in the next twenty-four hour period. The intravenous administration of the same dose resulted in a fall to normal levels within four hours. Twenty-four hours after injection, 10 mg. of the vitamin with bile was again given by mouth to prepare the patient for operation on the following day. At no time during the operation or in the postoperative period was abnormal bleeding noted. The prothrombin time remained within normal range, without further administration of the vitamin, until death on the third postoperative day. The results obtained in this case suggest that oral doses repeated at twelve hour intervals might have maintained the prothrombin level within normal limits. In case 2 a single intravenous dose of 10 mg. of synthetic vitamin K₁ resulted in a fall in prothrombin clotting time to a normal level within four hours. The clotting time remained within a normal range for six days after injection, despite the fact that an operation was performed during this period.

Extracerebral Malignant Metastasis Simulating Primary Carcinoma.—Bacon reports twenty-two proved cases of upper abdominal and mammary malignant neoplasms with metastasis to the pelvic peritoneal pouch. Of these, fifteen occurred in

men and seven in women; the average age was 54.5 years. Whereas the condition was advanced in all the cases in the series, it must be realized that such metastasis may occur early and be the only site of invasion. The condition is of importance in that it is not extremely rare and the symptoms may not direct attention to the primary site, because the extrarectal process may be incorrectly diagnosed and a radical extirpation performed. The primary growths were found most frequently in the stomach. Twenty-one of the tumors were adenocarcinomas and one was a sarcoma. Although misinterpreted in many instances, the rectal growths were palpated. This can be attributed to the fact that the more recent graduates have learned that no physical examination is ever complete without a thorough digital and proctosigmoidoscopic examination.

Acquired Atelectasis. W. H. Maddox, Wauseon.—p. 1320.

Acquired Atelectasis.—Maddox points out that massive atelectasis may be caused in traumatic cases by contraction of the bronchial musculature through shock to the pulmonary nerves (vagus plus sympathetic). This causes the smallest bronchioles to collapse and their walls to adhere, much of the air in the alveoli and bronchioles having been forced out by strong contraction of the muscles of expiration and by the narrowing of the bronchi and bronchioles by contraction of the intrinsic bronchial muscles aided by contraction of elastic tissue. In some cases of postoperative collapse, bronchial plugs are present in the main or smaller bronchi. When such plugs are not present, atelectasis may occur from stasis in the pulmonary arteries. This begins in the smallest branches and is favored by impairment of the general circulation and by interference with the amplitude of respiratory movements. This in turn favors reduction in vital capacity and other factors (high diaphragm with compression of the bases, fear of pain, sedatives, the maintenance of one position and the like). All patients with post-operative pulmonary symptoms should have the benefit of repeated roentgenography.

Zinc Peroxide in Treatment of Diabetic Gangrene.—Diluted solution of sodium hypochlorite and other hypochlorites do not act favorably on tissues which have impaired circulation, as in diabetic gangrene of the extremities. They inhibit the development of granulation tissue and thus delay the reparative process. Zinc peroxide, Meleney states, markedly inhibits the growth of the hemolytic streptococci and all anaerobic bacteria, including the organisms causing gas gangrene and the anaerobic streptococci. It neutralizes or inactivates the toxins formed by these organisms and at the same time encourages the reparative process by the stimulation of granulation tissue. Zinc peroxide, which is a white powder, should be suspended in sterile distilled water and applied to every part of the wound surface. The wound should then be covered with fine meshed gauze soaked in the same material. This should be covered with compresses saturated with sterile distilled water and these compresses in turn covered with petrolatum gauze or some other impermeable material to prevent evaporation. The dressing should be changed every twenty-four hours, the old material irrigated off, and a new dressing applied. It is important to use material which has been proved to be effective in the production of oxygen, and it is essential that adequate contact be obtained between the zinc peroxide suspension and every part of the wound surface. The use of sulfanilamide is indicated in addition to the zinc peroxide if hemolytic streptococci are present. If hemolytic streptococci and anaerobic organisms are present at the site of amputation, zinc peroxide should be used as a prophylactic to prevent the development of infection in the stump, or if infection has developed it should be used as early as possible to control it. If reamputation is necessary, it should be used immediately to prevent infection in the second operative site.

Hepatectomy, Plasma Prothrombin and Vitamin K.—Andrus and his associates performed complete hepatectomy in experiments with six dogs. They say that the precipitate and continuous fall in the plasma prothrombin which followed hepatectomy is evidence that the liver, under normal conditions, is concerned in the continuous formation of prothrombin. Further evidence that the liver is the organ which, in the presence of vitamin K, forms prothrombin is that instillation of a large amount of this vitamin into the duodenum during operation fails to alter the typical decreasing curve of the plasma prothrombin after hepatectomy.

Sensitization of Bakers to Flour.—Van Dishoeck and Roux estimated the occurrence of asthma, vasomotor rhinitis and eczema due to sensitization to wheat, rye, oat, corn or/and other flour among 262 unselected bakers and millers. All these workers were tested with the scratch method. A large number of persons were also tested for sensitiveness to ammonium persulfate. Sixty-six (25 per cent) of the bakers and millers were sensitive to flour. Among the 196 flour workers with negative reactions, ailments of the respiratory tract or eczema were exceptionally rare. On the other hand nearly all the sixty-six workers with positive cutaneous reactions were suffering or had suffered from one or more flour illnesses. Omitting exceptional cases, it seems that the flour illnesses, vasomotor rhinitis, asthma and eczema, are usually associated with positive cutaneous reactions to flour proteins. Of the sixty-six hypersensitive persons fifty-two gave positive and fourteen negative reactions to wheat flour. These fourteen reactors were sensitive only to oat or to rye flour. If investigations had been restricted to wheat only negative results would have been obtained in 21 per cent of the cases of flour illness. Hypersensitiveness to flour is most probably an inhalation allergy like that due to dust or pollen. From the personal histories of the sensitized flour workers, symptoms had developed in 37 per cent within the first five years of employment and within ten years in the remainder. Bakers, in small bakeries especially, were sensitized when still young. Only ten of the thirty patients with active eczema tested gave a positive reaction to ammonium persulfate. Therefore ammonium persulfate does not appear to be the primary cause in every case of flour hypersensitiveness, as suggested by some workers. On the contrary, the authors think that sensitization to flour is the main cause of the flour illnesses, including flour eczema, and on this ground in some cases an epithelial persulfate hypersensitiveness also develops. In all their cases of persulfate hypersensitiveness a strong positive flour hypersensitiveness was present. The

observations suggest that improvement in the hygienic conditions in bakeries, especially in the small ones, is desirable so that early allergic examinations of the bakers might be useful in detecting impending illnesses due to flour. Desensitization with the extremely potent proteose constituent of wheat, with encouraging results, has been tried.

Systolic Clicks Due to Left-Sided Pneumothorax.—Scadding and Wood, in the past two years, have observed cases which presented extra sounds during the cardiac cycle in association with shallow left-sided spontaneous pneumothorax. The extra sounds were of a clicking character and were usually best heard in the region of the apex beat. The sounds were usually single clicks and then occurred in the systolic part of the cycle; occasionally a more complex extra sound during systole or an additional less prominent diastolic sound of similar character might be heard. The systolic clicking element was the most striking. The sounds varied both in intensity and in timing with small changes in posture and were at times loud enough to be audible to the patient and to bystanders. The pneumothorax was of the benign nontuberculous type and was absorbed without incident, the sound disappearing when the pneumothorax was absorbed or earlier. The clicks have not been heard in association with larger pneumothoraces. In four cases of exudative pulmonary tuberculosis of limited extent, which were to be treated by left-sided artificial pneumothorax, the induction was performed with a smaller volume of air than usual and careful observation made during and after induction for the occurrence of extra sounds. In two of the four cases loud systolic clicks were produced. In the other two, though soft extra sounds were transiently audible on careful auscultation in various postures, they were not striking enough to be comparable with the sounds heard in the cases of spontaneous pneumothorax. The authors review the two cases of artificial pneumothorax in which the loud systolic clicks were heard. The sounds produced in these cases were similar in quality and timing to those observed in the cases of spontaneous pneumothorax. In both cases the introduction of more air rapidly caused the extra sounds to disappear. The authors point out that previously recorded cases in which transient loud noises synchronous with the heart beat were associated with the sudden onset of pain and dyspnea and with the appearance of air in abnormal situations in the tissues seem to fall into two distinct groups: (1) sounds in association with left-sided pneumothorax and (2) sounds in association with mediastinal emphysema. When the sounds were crunching, churning or crackling and might be heard as well in diastole as in systole, interstitial emphysema of the mediastinum was constantly present. The mechanism of production of the sounds in mediastinal emphysema is obvious. In shallow left-sided pneumothorax, the authors think the sounds are made by the forcible separation of the visceral and parietal pleura during cardiac systole, when the small air bubble in the pleura is in such a position that it can be moved by the cardiac pulsations—a mechanism similar to that of production of the consonant t. This hypothesis explains the presence of the sound only with small pneumothoraces, its disappearance if more air is introduced, and its extreme sensitivity to changes in posture. Several other hypotheses have been advanced to explain these sounds. Regarding the clinical importance of the extra sounds, the authors say that the syndrome may be most alarming to the patient and to his relations and may mislead the physician into making a diagnosis carrying a grave prognosis; for, unless the peculiar nature of the added sound suggests the advisability of x-ray examination, the spontaneous pneumothorax is likely to remain undiagnosed. The syndrome is of interest also in relation to systolic gallop rhythm.

Histologic Changes in Ménière's Disease.—In a previous article Hallpike and Cairns gave a description of the pathologic observations in the temporal bones of two typical subjects of Ménière's syndrome. Certain peculiar changes were disclosed in the labyrinth and the changes were considered to support the view that the disorder was due to specific disease of the labyrinth itself. The pathologic changes of the temporal bones of a third case, examined by Hallpike and Wright, are reported. On examination the tympanic membranes were normal, and hearing distance for the conversational voice was apparently normal on the right side but on the left side it was reduced to 6 feet. Bone conduction for a tuning fork was diminished on the left side and the audiogram showed a considerable high tone loss on the left side with normal hearing on the right. The tonsils were enlarged and grossly infected, and clinical and x-ray examination showed a bilateral antral sinusitis. The tonsils were removed and an intranasal opening was made into the antrum below the inferior turbinate on either side and in addition a limited submucous resection of the septum was performed to facilitate antral drainage. The patient eventually died, five weeks after the operation, as a result of repeated secondary hemorrhages. In the previous report the view was advanced that the primary mechanism of the disease was an obstructive distention of the endolymph system. This distention occurred in the present case. The peculiar nature of the changes makes it reasonable to regard them as constituting the essential morbid anatomy of a specific disease of the labyrinth. The relatively slight degree of the endolymphatic distention in the present instance and the absence of changes in Corti's organ or in the stria vascularis such as were disclosed in both of the cases previously reported are considered in greater detail. In both particulars it seems likely that the principal factor involved was the short duration of the disease. Six months elapsed between the first attack of vertigo and death. With regard to the extent of the endolymphatic distention, in the two previous cases the blocking of the scala vestibuli by the distended scala media was complete and this, it was suggested, was an essential part of the mechanism of the vertiginous attacks. This suggestion does not appear to be supported by the finding in the present subject of an incomplete distention of Reissner's membrane. Nevertheless the possibility exists that the distention found might well be subject to a rapid increase to the point of complete obliteration of the scala vestibuli and that such an increase might occur within a prodromal period of some hours preceding an attack of vertigo. This possibility is supported by the finding of marked folds in Reissner's membrane and for this reason it does not seem necessary at present to discard the suggestion in question. As to the absence in the present subject of changes in Corti's organ or in the stria vascularis, in addition to the minor character of the microscopic changes which would be likely to occur in the early stages of the disease, account must also be taken of a certain transience of these changes which would well accord with the fluctuating character of the deafness emphasized by Crowe. Such transience on the part of the changes in Corti's organ introduces a chance factor which would play an important part in determining the results of microscopic examination. Should this factor operate unfavorably then it seems likely that the minor changes which may be present in Corti's organ in the early stages of the disease will always defy microscopic demonstration, particularly when, as in the present instance, they are further obscured by the artefacts of postmortem degeneration.

Surgical Treatment of Arterial Hypertension.—Fontaine and Mayer review the clinical history of a woman aged 54 who had had hypertension for more than ten years and who had had already three cerebral attacks with paralysis aphasia and other symptoms. The treatment consisted of adrenalectomy, splanchnicectomy, with high lumbar sympathectomy, all associated with denervation of the renal pedicle, with ablation of the aorticorenal ganglion and completed by decapsulation. The operation was made only on the left side. After the operation the arterial tension decreased, but later there was again a progressive increase up to the preoperative figures. However, the functional amelioration persisted at the end of ten months. The benefit which the patient derived from the operation is manifested especially by the suppression of certain disagreeable subjective symptoms, such as headaches, giddiness and murmurs. Furthermore, the paroxysmic hypertensive crises, which represent such a grave danger for patients with permanent hypertension, disappeared after the operation.

Differential Diagnosis of Arterial Embolism.—Funck-Brentano says that in the presence of an acute arterial occlusion an early etiologic diagnosis is of vital importance, because only extreme rapidity of diagnosis permits the proper treatment, which alone makes it possible in most cases to preserve the function, prevent gangrene and avoid amputation and the resulting cardiac decompensation. Reviewing the clinical symptoms that are accepted as typical he mentions among the subjective signs the brutal pain, which is at first localized and then spreads toward the distal portion of the member; also the sensation of cold and the numbness in the member. Of the objective signs he mentions disappearance of the pulsation, discoloration of the skin, local cutaneous coolness, diminution or abolishment of the reflexes, abolition of movements and perturbation in the sensibility. He also stresses oscillometry as an important diagnostic aid. However, in spite of this wealth of symptoms the differential diagnosis of arterial embolism remains extremely difficult, and the author does not share the optimistic assurance of many surgeons who regard the diagnosis as easy. To explain his stand he reviews the following points: 1. Examinations like oscillometry may lead to errors. 2. The picture of arterial embolism may differ greatly from that regarded as classic. 3. The classic picture of arterial embolism can be realized by lesions other than embolism. In this connection the author points out that phlebitis and arteritis may exhibit symptoms similar to arterial embolism. 4. The anamnestic information does not always suffice to affirm the origin of arterial occlusion.

- Hematologic Investigations on Medullary Biopsy. W. de Weerd.—p. 297.
- *Antithyroid Action of Estrogen in Clinic. J. Lederer.—p. 326.

Antithyroid Action of Estrogen.—Lederer points out that the frequent appearance of goiter in women at puberty, gestation, lactation or the menopause directed attention to the relation between the ovary and the thyroid. Furthermore it has been

observed that, in exophthalmic goiter as well as in myxedema, disturbances of menstruation are likely to occur. Although the existence of a relation between ovaries and thyroid cannot be doubted, its mechanism is complex and abounds in contradictions. Following a brief review on the effect of injections of estrogen on the activity of the thyroid, the author reviews the history of a woman aged 36 who had been well until ten years before, when an exophthalmic goiter developed which failed to yield to medical treatment and later subtotal thyroidectomy was performed. The patient improved so that she could resume her normal activities. Several years later adnexitis developed and total hysterectomy became necessary with bilateral ovariectomy. Following this the symptoms of exophthalmic goiter recurred. Various measures such as roentgen therapy, compound solution of iodine, diiodotyrosine and even estrogen in a quantity of 10,000 units a week failed to improve the symptoms of exophthalmic goiter. Then it was decided to try estrogen alone in large doses. The individual dose was 5 mg. During the first week 25 mg. was given, during the second and third weeks 20 mg. each, during the fourth week 15 mg., during the fifth week 10 mg., and during the sixth to eighteenth week 5 mg. each. This treatment produced a rapid improvement. The author admits that it would go too far to conclude from this case that estrogen is the future treatment of hyperthyroidism. However, in the cases in which ovarian and hypophyseal dysfunction are involved, estrogen might be helpful.

Treatment of Psoriasis.—Incedayi and Ottenstein investigated the cholesterol metabolism in three cases of psoriasis. In view of the fact that recent opinions localize the disturbance in the lipid metabolism not only in the liver but also in the adrenals, the authors decided to try treatment with a preparation of adrenal cortex in combination with a diet that was deficient in potassium. The effect was surprisingly favorable in all three cases. However, no conclusions concerning the etiology of psoriasis can be deduced from these observations.

*Premenstrual Salivary Syndrome. W. Racine.—p. 1204.

Premenstrual Salivary Syndrome.—Racine presents brief histories of four women who observed tumefaction of their salivary glands four or five days before the onset of menstruation. The swelling subsided with the onset of the flow. In one woman the two submaxillary glands were swollen, in another one the two parotid glands and in the other two one parotid and one submaxillary gland. Simultaneously the women had an abnormal swelling of the breasts. It is noteworthy that all the women had undergone gynecologic interventions (unilateral ovariectomy, curettage or ligation of the tubes). The premenstrual appearance of the swelling of the salivary glands suggests a connection with the ovarian function and the author reasons that an insufficiency of the corpus luteum hormone is responsible. Consequently he decided to give injections of progesterone every other day during the ten days preceding the onset of menstruation. These injections prevented the appearance of the tumefaction of the salivary glands as well as the swelling of the breasts. One of the women was given the treatment four times with the result that for two years now the salivary symptom has not reappeared. Two other patients have to repeat the treatment during every premenstrual period, otherwise the salivary symptom returns. Although the treatment of the fourth patient prevented the appearance of the salivary symptom, the treatment was contraindicated because it diminished the diuresis and augmented the edemas; this patient had chronic nephritis.

*Glycemia and Glycorrhachia After Insulin Loading in Diabetes. G. Virel.—p. 537.

Glycorrhachia After Insulin Loading in Diabetes.—Vitale followed the behavior of dextrose in the blood and the cerebrospinal fluid of ten patients who were suffering from diabetes mellitus. The repeated determinations were done by the Hagedorn-Jensen method, before and after administration of a subcutaneous injection of 40 units of Richter insulin. The author found that the amount of dextrose in the cerebrospinal fluid of diabetic patients is increased in comparison with normal figures (0.001 and 0.0005 Gm. of sugar respectively to each hundred cubic centimeters of cerebrospinal fluid). Dextrose in both the cerebrospinal fluid and the blood diminish after administration of the injection of insulin. Diminution begins simultaneously. It takes place rapidly and in moderate figures in the blood and slowly and in large figures in the cerebrospinal fluid. The lowest figures of dextrose in the blood appear two or three hours after injection of the insulin, after which glycemia increases again. The lowest figures of dextrose in the cerebrospinal fluid appear five or six hours after the injection and when glycemia has been for several hours near the figures existing before the injection. In one of the cases a comatose condition, lasting about twenty minutes and spontaneously subsiding, developed during the few minutes that glycorrhachia was at the lowest figures (almost an absence of dextrose in the cerebrospinal fluid) and glycemia was near those existing before the injection of insulin.

Syndrome of Nasociliaris Nerve (Charlin's): Cases. F. Caldera.—p. 215.
Cirsoid Aneurysm: Critical Study. L. Novara.—p. 283.

Removal of Calculi from Pelvic Segment of Ureter.—Brancati's operation is a modification of Bergmann's ureterolithotomy. It is performed under spinal anesthesia and consists of incision of the abdominal wall exactly on the inguinal canal (on the side of the calculous ureter, the incision being made from the anterior iliac spine to the external edge of the external muscle), opening of the inguinal canal and of the fascia transversalis, section of the epigastric blood vessels (previously ligated), separation of tissues of the pelvic peritoneum so as to have the ureter isolated from the tissues, incision of the ureter, removal of the calculi, suture of the ureter with catgut, and plastic reconstruction of the canal and of the abdominal wall by Bassini's technic (which is used in the reconstruction of the structures after operation for inguinal hernia). When drainage is resorted to the reconstruction of the abdominal wall is performed by Mugnai's technic. The author reports six cases with calculi at either the right or the left pelvic segment of the ureter of either sex, with satisfactory results from the operation.

*Blood Transfusion with Large Doses of Arsphenamine in Grave Puerperal Infection. A. Peralta Ramos and A. A. Montes.—p. 2419.
Bilateral Bronchiectases: Insufficient Left Lower Lobectomy. S. Finocchio, A. Rissotto and H. D. Aguilar.—p. 2426.

Blood Transfusion with Arsphenamine in Puerperal Infection.—Peralta Ramos and Montes report satisfactory results from blood transfusion containing large doses of arsphenamine in six cases of grave puerperal infection. Sulfanilamide and immunotransfusion had previously failed in all cases. The technic is as follows: Arsphenamine 1.5 Gm. is dissolved in from 3 to 4 cc. of dextrose solution, which is added to from 200 to 300 cc. of weakly citrated blood (20 cc. of a 2 per cent solution) for further dilution and then administered to the patient by slow transfusion. The ampule which contains the injecting solution is placed at a height of 1.6 meters. The blood is administered by the drip method with a needle 1.8 mm. in diameter (never larger). It is given at a rate of twenty drops a minute so as to instill a dose of 0.01 Gm. of the drug a minute. Lowering of the temperature of the injecting solution during transfusion should be prevented. At the

end of the transfusion (through the same needle) from 50 to 80 cc. of a hypertonic solution of dextrose is administered and an intramuscular injection of 0.1 Gm. of vitamin C and extract of total liver is given. The treatment is repeated on the following day. The treatment was well tolerated and successful. Two treatments were administered in all cases, in spite of the fact that control of the symptoms and of the infection became evident immediately after administration of the first transfusion with arsphenaminized blood.

Functional Mastopathy. J. Benzadon.—p. 1158.

*Treatment of Acute Gonorrheal Urethritis. V. A. Gorla.—p. 1198.

*Hyperthyroidism Without Goiter. C. Alvarez.—p. 1209.

Gonococcus Vaccines in Acute Gonorrhea.—Gorla used Nicolle and Blaizot's vaccine, which contained between 200,000,000 and 1,500,000,000 gonococci, in seventy-five cases of acute urethritis with or without complications. The vaccine was given every other day or at intervals of two days up to six doses, after which lavages were given for one month if the urethral secretion persisted. Of forty-nine cases of acute urethritis without complications the gonococcus disappeared from the urethral secretion before ten days in thirteen, before twenty days in twenty and after twenty days in sixteen. The secretion stopped before one month in twenty-three cases and after a month in twenty-six cases. In six cases each of acute urethritis with orchiepididymitis or cystitis and in three cases of urethritis with cystitis, clinical and bacteriologic recovery was obtained before two months. In all cases the satisfactory results have lasted from six months to two years after discontinuation of the treatment. Urethral secretion is not present in any of the cases. According to the author gonococcus vaccines, when administered intravenously, give better results than when administered otherwise. It is advisable not to prevent shock from the vaccines, as it is specific and of therapeutic value. Gonococcus vaccines cannot be administered intravenously to ambulatory patients. The patient has to rest in bed for the first few days of administration of the treatment and again on the day on which the vaccine is administered. The contraindications are heart disease, tuberculosis, asthma, cardiorenal diseases and old age.

Hyperthyroidism Without Goiter.—Alvarez studied a large number of cases of hyperthyroidism in the absence of goiter. He calls attention to the frequency of the condition in the presence of various diseases, infections and physiologic phases of life, especially tuberculosis, pure arterial hypertension and the menopause.

Action of Ultraviolet Radiation on Epinephrine.—Konzett and Weis point out that Ewing and his collaborators, in examining the action of ultraviolet radiation on epinephrine, synephrin and ephedrine, observed a contradictory behavior. Whereas epinephrine was found to lose its intensifying action on the blood pressure and the blood sugar, the efficacy of synephrin was found to increase in this respect. Ephedrine responded like epinephrine with a loss. Ewing and his co-authors assumed that this change in action was due to oxidative processes but made no attempt to explain the contradictory results in epinephrine and synephrin. Konzett and Weis assume that the change in the action of synephrin is due to the fact that epinephrine is formed in it under the action of ultraviolet rays. In this paper they report experiments which they carried out to explain this problem. Summarizing their observations they state that epinephrine loses its blood pressure action as the result of ultraviolet irradiation. The fluorescence of the epinephrine solu-

tions decreases in the same measure as does the blood pressure action. Under the influence of ultraviolet irradiation, the epinephrine solutions assume at first a reddish color, then a reddish yellow one and finally they again become colorless. The destruction of epinephrine takes place even under exclusion of oxygen. From synephrin there develops under the influence of ultraviolet rays a body with an intense pressor effect, which on biologic and chemical analysis proved to be epinephrine. The maximal value of epinephrine in the irradiated synephrin solutions amounts to from 8 to 10 per cent of the originally existing synephrin; in the concentrated solutions this maximum is obtained later than in the diluted ones. However, under ultraviolet irradiation epinephrine is not only formed but also destroyed in synephrin solutions. At first its formation predominates, but later with growing exhaustion of the stores of synephrin the destruction of epinephrine predominates. Oxygen is absolutely necessary for the transformation of synephrin into epinephrine.

Oxygen Intoxication.—Becker-Freyseng and Clamann direct attention to the fact that an oversupply of oxygen can be harmful for the animal organism. This observation, which was made by Lavoisier in 1794, was subsequently corroborated by others. Following a brief review of the literature the authors report their own observations in experiments on themselves and on animals. They stayed for sixty-five hours in a chamber the air supply of which contained 90 per cent of oxygen. Rabbits, guinea pigs and mice were subjected to the same conditions, but the authors discuss chiefly the observations made on themselves. During the first twenty-four hours they had no complaints, but changes in the alveolar carbon dioxide tension developed almost immediately after the onset of oxygen inhalation. At the end of twenty-four hours pathologic changes appeared; there were nervous symptoms, such as formication in the fingers and toes and paroxysmal tachycardia. After about sixty hours one of them had attacks of vomiting, which was probably of central origin. Pulmonary symptoms were absent in one case but in the other one symptoms of febrile bronchitis developed and the vital capacity was simultaneously reduced from 4,000 to 2,700 cc., probably as the result of hyperemia of the lung. The observations on healthy human subjects corroborate those made in animal experiments. As in animals, the changes are noticeable in the respiratory tissue of the lung, in the central nervous system and in the blood. After discussing the probable mechanism of the pulmonary and hematic changes, the authors say that the fever, the leukocytosis with deviation to the left, the increased sedimentation speed of the erythrocytes and the febrile increase in the pulse rate are secondary complications of the inflammatory changes in the pulmonary tissue. The question why there were differences in the reactions of the two persons cannot be definitely decided. The authors regard it as more important that both had a decreased vital capacity as the manifestation of inflammatory changes in the lungs and that both had nervous symptoms.

Duyven de Wit.—p. 1423.

Metrazol in Intoxications Caused by Soporifics.—In the last eighteen months, forty-two cases of poisoning with soporifics were treated at Heinrich's clinic by intravenous injections of metrazol. Other patients with the same type of poisoning were treated with the customary procedures. All of the forty-two patients who were treated with metrazol had lost consciousness and were entirely unresponsive. The author thinks that although the number of cases treated with metrazol is compara-

tively small, the favorable results which were produced cannot be regarded as accidental. Four patients were not benefited, but three of these were moribund at the time of hospitalization. In comparing the results of metrazol therapy with those of other therapeutic methods, the author found that the mortality from intoxications with soporifics is much lower after treatment with metrazol than with other methods. The majority of the patients responded to a single intravenous injection of from 3 to 5 cc. of a 10 per cent solution of metrazol. This is the dose which the author administers to patients who are unconscious but who react to pinching. The patients who are unresponsive to pinching are given from 8 to 10 cc. of metrazol. If this injection does not awaken the patient, a second injection is made after a short interval (about fifteen minutes) with the same or a slightly larger dose. If signs of convulsion are apparent after the first injection, the second dose should be smaller (5 cc.). If awakening does not follow after a second or even a third injection, treatment should be restricted to measures which support the circulation. However, even the patients who do not respond to two or three injections at short intervals should be given at least two or three injections of large doses of metrazol in the course of the day. With this treatment, awakening may perhaps be obtained in from two to three days. The reviving effect largely depends on the rapidity of the injection; that is, a small dose rapidly injected produces the same result as a large dose that is injected slowly. As in the convulsion therapy with metrazol, the rate of injection is usually 1 cc. a second; but sometimes the injection is made with greater speed. The author watched for complications resulting from this treatment and found that epileptiform attacks may result from excessive doses or from too rapid injection but that they are of no importance, for in these intoxicated persons the convulsions are not as severe or as lasting as they are in persons who are not under the influence of narcotics. The electrocardiogram is not changed by the intravenous injection of large doses of metrazol. The author emphasizes that the treatment is not suited to patients with carbon monoxide poisoning or to patients with morphine intoxications. However, in severe cases of alcohol intoxication the intravenous injection of from 3 to 5 cc. of metrazol proved effective.

Influence of Cold on Carbohydrate Metabolism.—Samaras carried out experiments on the effects of cold on carbohydrate metabolism in male white rats. Several days before the experiments the animals were given a diet with a high carbohydrate content and five hours before they were given 0.5 Gm. of dextrose for each hundred grams of body weight. The dextrose in the form of a 25 per cent aqueous solution was introduced through the stomach tube. This dextrose was given in order to effect a maximal filling of the carbohydrate depots. Twenty-four hours before the cooling experiment the urine of the animals was tested for creatine and only those were used in which the urine was free from creatine. Immediately before the cooling experiment the temperature of the animals was measured. The cooling was effected by placing the rats in water that had a temperature of from 2 to 3 C. (35.6 to 37.4 F.). Care was taken that the head was not under water. The animals remained in the cold water for from five to ten minutes. First there were violent movements with the extremities, then the animals became fatigued and finally they fell into a collapse-like faint. After withdrawal from the water, the temperature was determined at definite intervals. To determine the changes in the glycogen content of liver and muscles, groups of five animals each were killed after intervals of one, two, four, nine, twenty-four and

thirty hours. The author found that the sudden reduction of the body temperature to less than 22 C. (71.6 F.) produces a temporary moderate increase in the blood sugar content, an almost complete disappearance of hepatic glycogen and reduction in the muscular glycogen amounting to almost 50 per cent. Finally there is a creatinuria which persists for from two to three days. These are manifestations of the chemical heat regulation, which aims to restore the lost heat as soon as possible. New heat is formed first by the combustion of the preformed stores of carbohydrates in the organism. However, it seems probable that the combustion of sugar plays an important part only immediately after the cooling process. Many factors indicate that the combustion of fat soon takes the place of the sugar combustion and that most of the newly formed heat can be traced to fat combustion.

Case of Death During Treatment with Arsphenamine: "Apoplexie Séreuse." K. Rambøl.—p. 3447.

Traumatic Disorders of Brain and Their Medicolegal Significance.—Harbitz discusses the anatomic manifestations in 165 cases, including sixty-two necropsies which he himself made. Epidural and extradural hemorrhages occurred in twenty-seven cases, with simultaneous hemorrhages in the interior of the brain in only four. Subdural hemorrhages were found in ninety-three cases and were massive in nineteen; intermeningeal or subarachnoid hemorrhages occurred in 112 cases, often with subdural and cortical hemorrhages. Cortical hemorrhages were seen in most of the cases. "Central" hemorrhages were established in the central ganglions in eighteen of his personal cases, and simultaneously or independently in the pons varolii or around the aqueduct of Sylvius in sixteen, in all in about one third of his cases. These hemorrhages were regularly found in connection with fracture of the skull and bleeding in the brain membranes and in the cortex; they were usually inconsiderable, were perivascular and under the ependyma and in most cases were demonstrable only microscopically. Hemorrhages in the medulla oblongata appeared in twenty-three of his personal cases, or about 37 per cent. They were often absent in cases with small lesions of the head and especially when there were simultaneous lesions of the chest and abdomen with internal hemorrhage. Usually they were demonstrable only microscopically and were perivascular, without destruction of nerve tissue, with simultaneous perivascular hemorrhages in other central parts of the brain. There were regularly other marked intracranial changes: large skull fractures, hemorrhages, often considerable, in the brain membranes and especially large cortical hemorrhages and now and then general brain edema. The author assigns little significance from the medicolegal point of view to the inconstant perivascular hemorrhages and asserts that similar hemorrhages have been established in the medulla oblongata in cases of sudden nontraumatic death and have been absent in cases of fatal trauma of the head with symptoms of concussion. He does not regard the base of the fourth ventricle as a place of predilection for such hemorrhages and did not in any of the 165 cases find an isolated massive hemorrhage in the medulla oblongata which could be considered as certainly or very probably of traumatic origin and the cause of death. Five so-called nearly pure cases of concussion of the brain are described, in which, mainly by microscopy, small hemorrhages were established in various parts of the brain, not usually in the medulla oblongata. In his opinion no definite anatomic changes can be regarded as the essential and certain cause of the symptoms of concussion of the brain. He stresses that brain edema when present is an expression of general circulatory disturbance of great importance in explaining the phenomena and eventually the cause of death. He doubts that fatal traumatic disturbances of the brain occur without anatomic changes and maintains that on the whole there is no sharp division from the anatomic point of view between contusion of the brain and concussion.

FIFTEEN YEARS' OBSERVATION OF CHILDREN WITH RHEUMATIC HEART DISEASE

WILLIAM D. STROUD, M.D.

AND

PAUL H. TWADDLE, M.D.

PHILADELPHIA

It again seems of interest to present a summary of our results at the Children's Heart Hospital of Philadelphia in caring for children who have been admitted threatened with or suffering from cardiovascular damage as a result of rheumatic fever. A previous report¹ presented data from the Children's Heart Hospital for the period June 1922 to January 1932. The present review is a study of the cases seen between June 1922 and June 1937.

People in the United States assumed an early role in the institutional care of children with heart disease and have established a number of institutions, among them the House of the Good Samaritan (Boston), the Irvington House on the Hudson (New York), Sunset Camp (Bartlett, Ill.), Ridge Farm (St. Louis) and the Children's Heart Hospital (Philadelphia). England, under a nationwide system, has made remarkable progress in developing resources for the care of children with heart disease in convalescent hospitals, and it was estimated in 1938² that there are 1.7 beds for each thousand elementary school children.

It has been stated that the ultimate results obtained through returning children from general hospitals to their homes or foster homes and the follow-up treatment through social service and visiting nurse departments of these hospitals are as satisfactory as the results following treatment in convalescent institutions. The final answer to this must be delayed until further data are accumulated. This report will present our results to March 1939, but since our children have not all been followed an equal number of years we are faced with the common problem of finding data with which a comparison can be made. We do feel that there are certain factors, evident at present, which justify the existence of care in a convalescent hospital:

1. Treatment varies with the individual case, but group control, under the instruction of a competent staff, provides that the medical care will be adequate and that the individual child's activity will be adjusted to the functional capacity of his heart. Such is the opinion

of Anderson and his co-workers³ at Cincinnati, who add that "of great assistance in establishing the new routine of living were the institutions such as the Children's Convalescent Home, the Condon School for Crippled Children and the County Chronic Disease Hospital."

2. Jones⁴ emphasizes that a specialized, competently trained physician is desirable in handling cases of rheumatic fever, the training being comparable to that of those working with cases of tuberculosis.

3. In a group, children cooperate better in the rest treatment for this condition, and with teachers as a part of the staff it is possible to carry them along with their classes during their long convalescence.

4. Silver⁵ studied a small group of patients under care at a residential school for cardiac children. Most children adapted themselves well emotionally and socially to their physical handicap. "The utilization of a residential school for cardiac children," he claims, "offers an opportunity for the establishment of a successful mental hygiene program and leads to the disappearance, in most of these children, of undesirable mechanisms established in the home."

5. Parents as well as the children are educated, through visiting periods, lectures and personal interviews, on the importance of rest, diet, hygiene, dangers of contact infections and the like.

6. A home environment which may be a definite handicap is eliminated. Paul and Salinger⁶ have noted the spread of rheumatic fever in families, and an infectious basis for the disease is suggested. Many times, too, parents have complained that with large families and inadequate finances they cannot alter their household routine to care adequately for their child.

7. Furthermore, such hospital groups offer valuable material for the instruction of medical students as well as graduate students interested in this type of work. Research into the value of newer methods of treatment and prevention of reactivations of rheumatic fever is assisted by a series that can better be controlled.

Miss Elizabeth Knowles, financed by the Philadelphia Heart Association, has made an intensive effort to get in touch with the 685 children who have received convalescent care at the Children's Heart Hospital from 1922 to 1937. This figure (685) does not include eighty-eight children who are excluded from the study because they stayed at the hospital less than one month or because they had congenital heart disease or were diagnosed as not having heart disease.

This work was done through the Robinette Foundation of the University of Pennsylvania and the M. W. Stroud Jr. Fellowship in Cardiology of the Pennsylvania Hospital.

In a report in 1930⁷ the requirements for admission to the Heart Hospital were given as follows:

1. Age limit: Boys, 3 to 12 years; girls, 3 to 13 years.
2. Children shall have either possible or potential cardiovascular disease.
3. No patients who have had congestive circulatory failure or with a hopeless prognosis shall be admitted.
4. Before admission each child shall spend at least two weeks in a hospital.
5. So far as possible all foci of infection should be removed.
6. Parents shall agree that children will remain in the hospital from three to six months or longer, at the physician's discretion.

The group of 685 children included 334 boys and 351 girls—a ratio influenced by the requirements for admission. We were unable to locate 105 (15.3 per cent) of the group, and an additional 144 children (21 per cent) have died.

RACIAL DISTRIBUTION

A tabulation of the group according to race is presented in table 1. Its significance is questioned, however, when one realizes that nearly one half of the patients are sent from hospitals and physicians in South Philadelphia, where the Italian and Jewish populations are most concentrated, and that certain races are more prompt than others to avail themselves of these institutional advantages.

From other reports we believe that there is an apparent resistance among Negroes to rheumatic fever. Thus Ash⁸ found that in the clinic of the Children's Hospital in Philadelphia, where the white and Negro children are about evenly divided, the rheumatic children were 83 per cent white and 17 per cent Negro. Sutton,⁹ at Bellevue Hospital in New York, found the percentage of Negroes in the cardiac clinic only one third of the percentage of Negroes in the general pediatric clinic. Wilson and her co-workers¹⁰ found that "only 4.6 per cent of the children were colored although the clinic draws from a colored district." This paper refers to the work of Wood, Jones and Kimbrough,¹¹ who found

TABLE 1.—Racial Distribution

that rheumatic heart disease "seemed to be less common among the colored people than the white people in Virginia." In New York City⁹ there seems to be a susceptibility to rheumatic heart disease among the Italians, while the Jews are afflicted to a degree less than their general clinic percentage. The Irish apparently have a rather high tendency to rheumatism, although it is noted that the Irish in Ireland do not

have a high rate for heart disease. In Philadelphia, regardless of race, it was found that 0.91 per cent of public school children had organic heart disease.¹²

RHEUMATIC HEART DISEASE AND ABILITY TO WORK

Of the total group, 249 children (36.3 per cent) are attending school, and it is gratifying to find that 117 (17.1 per cent) are otherwise employed in spite of their cardiovascular handicap, while only thirty-nine

(5.7 per cent) who are able to work are unemployed. Table 2 presents a record of the children discharged from the hospital by sex and by ability to work, while table 3 records the ages to March 1, 1939, and the ability to work.

From the results it would be difficult to state that sex had any influence on the ultimate prognosis. This is in agreement with the general observations of Schlesinger^{12a} and with the experience at the Children's Hospital of Philadelphia,⁸ where the death rate for the sexes was similar to that of the group as a whole. There seems to be general agreement that infection with rheumatic fever is slightly more prevalent among females than among males.¹² The ability for activity as noted in table 3 among those living shows a tendency to decrease with the older age groups (82 per cent of those under 15 years and 67.4 per cent of those over age 15).

In evaluating the ability to work in relationship to the length of stay at the Heart Hospital, it should be noted that only the first admission is counted; the days following a period in a general hospital, where a patient may have been sent for an acute episode, are added to the days of hospitalization at the Heart Hospital, and the total stay is counted as one admission. The largest group of children (36.5 per cent) stayed from three to five months, and the next largest group (30.4 per cent) from six to eight months. In table 4 it is seen that of the 110 children who stayed less than three months a large number (41 per cent) are dead, and it may be assumed that this percentage would be increased if the fate of the remaining nineteen children were known. Many of this group of children were probably not fair selections for convalescent hospital care, for after a short stay they had to be returned to general hospitals because of advanced illness. Many

of the fatal cases were admitted during the first few years of the institution before a suitable basis for selection of cases was found.

Considering the groups able to carry on reasonably normal activity (in school, working, unemployed), it

As seen in table 5, the functional classification¹⁴ at the time of discharge supports this contention. It can be seen that 33.2 per cent of those who were hospitalized for from three to five months had symptoms at discharge (i. e. classes II A, II B, III). Similarly, 50.5

does not appear that a prolonged stay at the hospital has materially increased the number who are active, nor has the death rate been reduced (excluding those who remained from one to two months). Yet those staying longest were usually hospitalized in relationship to the duration of their rheumatic activity (mainly determined by the sedimentation rate of the blood) during their period of observation.

per cent of the children who remained in the hospital from six to eight months had symptoms at discharge; in the nine to eleven month group 55 per cent and in the group staying longer than a year 75.7 per cent. As has already been noted, many of those remaining

14. Criteria for the Classification and Diagnosis of Heart Disease, New York Tuberculosis and Health Association, New York, Sixth Printing of Third Edition, 1938 (Copyright 1932).

less than three months were discharged to general hospitals, and in this group 53.6 per cent were discharged with symptoms.

To follow further the functional classification at the time of discharge from the hospital, it is interesting to see how this factor has ultimately influenced the ability

assumption that, as a group, an early estimation of the functional capacity is an index to the prognosis.

Table 6 might serve to call attention to the importance of rehabilitation and placement in industry of those handicapped with cardiovascular disease.¹⁵ "It seems questionable whether physical effort is responsible for the production of cardiovascular disease or

plays as large a part in the progression of cardiovascular disease as has been previously believed. If this is true the training of cardiac patients and their placement in industry constitutes as great a responsibility for the physician as any other form of therapeutics—in fact in class I and II A a much more important responsibility than medication or other forms of therapy."

MORTALITY

Of our total number of children, 144 (21 per cent) have died. Another 15 per cent are either out of town or could not be located. Since we have felt that during the first few years of the institution the wrong type of case was accepted by the hospital and that the follow-up in these cases was inadequate, we are not surprised to find that the mortality rate for the first four and a half year period is unnecessarily high (table 7).

Thus eliminating the years 1922 through 1926 and determining the loss of life among our discharges from

† No history of rheumatic fever, chorea or endocarditis could be obtained.

‡ Age at primary manifestation unknown, or record of rheumatic history previous to admission not available.

1927 to 1937, we find a mortality of 14.8 per cent, or seventy-six deaths. Of this modified group only twenty-seven children (5.3 per cent) are out of town and thirty (5.9 per cent) have not been located. According to a report from the House of the Good Samaritan in Boston,⁴ 24.2 per cent of their 1,000 patients, with an average follow-up of ten years, are dead. In a ten year follow-up of 1,000 patients at the County Convalescent Heart Hospital for Children at West Wickham, England,¹⁶ for patients with acquired heart disease, there was a mortality of 12.3 per cent—an excellent record with only an additional 6 per cent of patients in poor health. In the first ten years (1920-1930) of the Irvington House¹⁷ 24 per cent of the patients had died at the time of the report. Coombs,¹⁸ reporting on 253 patients with cardiac infection in Bristol, England, showed that 21.4 per cent had died within ten years after the primary manifestation of rheumatic fever. This percentage is identical with that previously reported from the Children's Heart Hospital in the ten year study.¹ In a group of 395 patients

without institutional convalescent care reported on by Wilson, Lingg and Croxford,¹⁰ only 11.9 per cent had died in ten years.

A special study of the deceased patients was made in connection with this report. The cause of death was sought for each one of the 144 fatalities. A satisfactory report was obtained on all but two; in one of these death was said to be due to acute bronchitis and in the other case to "grip with complications." We assume that these were noncardiac deaths and they are so listed in table 8. This table reveals that congestive heart failure claims the largest group (104 patients); eleven apparently died of acute rheumatic infection without signs of decompensation, nine died of bacterial endocarditis (three acute and six subacute), nine died suddenly (one from a pulmonary infarct, five from

(Cincinnati),² 7.3 years—with one half of initial infections occurring between the ages from 6 to 9 years (New York),¹⁰ 7 years (New Haven),¹⁹ 10.2 years (England),¹⁸ 7 years (England),²⁰ 6.8 years (Philadelphia);⁸ at the Irvington House (New York)¹⁷ the mean age is 8 years, while more were infected at age 7 than at any other single age. Fifty-three per cent of our children who died had their first rheumatic attack at 7 years or earlier and 28 per cent had their first attack from 8 to 13 years of age, while the records do not give the information for the remaining 19 per cent for reasons cited in table 9.

The greatest mortality occurred between three to five years after the primary manifestation of rheumatic fever. Nineteen per cent of the 144 children lived less than three years and 48 per cent less than six years.

Also sterilized.

embolism and three from causes not definitely stated), five died of pneumonia and six died of noncardiac causes. Information obtained concerning the presence of auricular fibrillation in the fatal cases is rather meager. Two of the cases of sudden death were accompanied by auricular fibrillation (age of onset unknown), while in three there was no fibrillation, and for the remaining four this information was not learned. Among those who died of congestive heart failure, auricular fibrillation was present in thirteen and absent in nineteen and there was no record for the remaining seventy-two. Five patients had auricular fibrillation starting shortly before death; four had had fibrillations for some time—one for as long as five years. The ages of onset of auricular fibrillation were one at 7 years, one at 8 years, one at 11 years, three at 13 years, one at 16 years, one at 19 years and one at 23 years.

The youngest patient to die was 5 years old and the oldest 28 years. Eighty-one per cent of deaths occurred before the age of 16, with the heaviest grouping between ages 8 to 16. This may be significant for the surviving children, since 75 per cent of them are now over 16 years of age. It appears that the children who live through the adolescent period have a good chance of reaching maturity. Wilson and her associates¹⁰ note that at the age of about 12 years the tendency to acute infection begins to diminish. Schlesinger^{12a} stresses his conviction that puberty is the determining period at which the power of resistance to rheumatic infection increases, cutting down on the number of recurrences. One of our patients died of active rheumatic fever at 16 years of age but none at an older age.

There is uniformity of opinion as to the age at which rheumatic fever usually begins its course. In our group the largest number of first attacks occurred at the age of 7 years. From other studies the average ages at onset are 8 years (Boston)⁴ from 7 to 8 years

When the thirty cases are eliminated in which the duration of the disease is unknown, the percentage of patients living less than six years becomes 61. Eight children lived longer than twelve years, the oldest surviving twenty-one years after her initial attack at 7 years. There is no apparent indication in table 9 that the children in whom rheumatic fever occurred early in childhood have a shorter span of life than those in whom the onset of the disease came later. If the patients are divided into two subgroups, one with onset ages of 3 through 7 years and the other with onset

Seasonal prevalence of primary manifestations and reactivations of rheumatic fever. Three hundred and seventy-seven (46 per cent) of 816 primary infections and reactivations occurred between February and May.

ages of 8 through 12 years, those in the latter subgroup have the higher percentage mortality during the first six years of the disease. Wilson and her associates¹⁰ likewise found no apparent relationship between mortality and the duration of the disease. However, at the Children's Hospital in Philadelphia⁸ "there was a distinct drop in the death rate among the older children who were first taken ill between 9 and 11 years of age." Halsey,¹⁷ studying 203 children under insti-

tutional care, for whom an estimation of the duration after the onset of the disease to death could be determined found that approximately 16.2 per cent died in the fourth year of the disease; 25 per cent of deaths occurred within the first six years, and in two thirds the duration was less than eight years. Only one fifth of his patients survived ten years or more. Ash⁸ reports that, of ninety-three deceased children with clinic care, one third of the deaths occurred within the first year, 51 per cent within two years and 74 per cent within five years of the onset.

SEASONAL INCIDENCE

The dates of onset of 816 attacks of rheumatic fever, chorea and acute carditis were learned, and the accompanying chart shows that the largest number of attacks occurred in March, with a high incidence as well in February, April and May. Forty-six per cent of the 816 attacks occurred in these four months. The lowest number of attacks was in July, August and September.

It is of interest to know the seasonal incidence for one's locality and compare it with other reports. Coombs¹⁸ found a maximum incidence in England during the months of December and January. In a report from two hospitals in London and one in Glasgow,²¹ the highest incidence is in the three months November, December and January, with the lowest incidence in the summer months. Sutton⁹ reports that the peak in New York is reached in April, with the low incidence during October.

PREGNANCY

An attempt has been made to determine the effect of marriage and childbirth on the girls in this series (table 10). Of all those living whom we have been able to follow up, thirty-eight of the girls are married and two have had illegitimate children (one at 15 and one at 17 years). Thirteen of these forty girls have never been pregnant, but among the remaining twenty-seven there is a record of forty-seven pregnancies. None of those who are known to have died were married. Only one girl suffered definite congestive failure at delivery, and she has been sterilized. Two others showed slight symptoms of congestive failure during pregnancy but went through delivery successfully. "Other complications" include one case of hypertension with threatened abortion and one of severe hemorrhage at the time of the first menstrual period after delivery.

SUMMARY

1. Six hundred and eighty-five children threatened with or suffering from rheumatic heart disease who have been treated at the Children's Heart Hospital of Philadelphia, between 1922 and 1937, have been studied.

2. It is believed that available educational facilities, attention to hygiene, adequate medical supervision and ability to adjust the child physically and emotionally to his handicaps are factors to justify such convalescent institutional care, and further that opportunities for research and training are made available.

3. An apparent resistance among Negroes to rheumatic fever was noted but otherwise the evidence regarding the relationship of race to rheumatic fever did not appear to be significant.

4. Among twenty-seven girls who became pregnant, only one suffered definite congestive failure at delivery.

STOMACH LAVAGE IN THE DIAGNOSIS AND CONTROL OF TREATMENT OF TUBERCULOSIS

ASYA STADNICHENKO, A.B.

SEYMOUR J. COHEN, M.D.

AND

HENRY C. SWEANY, M.D.

CHICAGO

Meunier¹ in 1898 was the first to employ gastric lavage as a means of establishing the diagnosis of tuberculosis in infants and children. Although both his idea and his results were good, his work was almost forgotten until 1927, when Armand-Delille² and Vibert revived it. Since then Poulsen, Jensen and Husted³ and again Poulsen,⁴ Wallgren,⁵ Boer,⁶ Kereszturi and her co-workers,⁷ Sayé and his co-workers,⁸ Collis,⁹ Gourley¹⁰ and many others have used the method with very favorable results.

At first this method was used only on infants and children, as originally described by Meunier.¹ Clausen¹¹ has the distinction of being the first to report results on adults. As time went on the value of the method became more evident, and its usefulness has been established for diagnosis and for control of treatment not only of children but also of adults. Among others, Ulmar and Ornstein,¹² Gad,¹³ Levin,¹⁴ Bobrov,¹⁵ Stiehm,¹⁶ Boide and Simonin¹⁷ and Gullbring and Levin¹⁸ have reported work on adults.

At the Chicago Municipal Tuberculosis Sanitarium we have been doing stomach lavages on our adult patients whose sputum was negative for tubercle bacilli since February 1934. A preliminary report of this

work was made in 1935¹⁹ and 1937.²⁰ At present we present a series of 1,000 patients of whom 970 (97 per cent) were over 10 years of age. This is shown in table 1 and in the chart. This group of patients with negative sputum represents about 11 per cent of the total admissions to the Municipal Sanitarium from February 1934 to October 1938.

PROCEDURE

The patients arise in the morning but are not allowed any food or liquids. Before aspiration they are given 4 ounces (120 cc.) of sterile distilled water to drink. Immediately after the patients have swallowed the water a regular Ewald tube is passed and the contents of the stomach are aspirated, the whole procedure taking from fifteen to twenty seconds.

At first we used ordinary tap water, but this was criticized on the grounds that acid-fast bacilli may be found in tap water. Although we have never found a false positive result, nevertheless we now use boiled distilled water. Another factor that was thought might cause a false positive result was that the Ewald tubes and bulbs might not have been cleaned properly. We checked this by washing all the cleaned tubes and bulbs with sterile distilled water and treating the sediment as is usually done in a routine way. The results of this procedure showed an absence of any acid-fast bacilli on culture or on guinea pig inoculation. The method of sterilization of the bulbs and tubes is as follows: They are washed with hot water and then with tincture of green soap. Then they are immersed in 20 per cent saponated solution of cresol for forty-five minutes, after which the bulbs and tubes are washed again with hot water and dried. The basins are treated in the same way. We conclude, therefore, that after the tubes and bulbs are properly washed and sterilized they are free from any tubercle bacilli.

One of us (S. J. C.) has developed a special technic for passing the Ewald tube. The method is as follows: Insert a cold wet Ewald tube about 1½ inches (4 cm.) into the center of the patient's mouth. At the same time the patient is told to bite the tube lightly with his teeth and to breathe deeply through the mouth. The patient's head is flexed sharply so that his chin rests on his chest. The operator's left hand is placed around the posterior part of the patient's neck, applying a downward pressure. The position of the arm serves two purposes; first, it keeps the patient's head flexed on the chest; second, it acts as a vise and keeps the patient under control. The patient is told to release his bite on the tube, and as he does so the operator gradually and steadily passes the tube down with his right hand. The bulb is connected, and when fluid appears in the glass section of the tube it is immediately withdrawn. The whole procedure should not take more than fifteen to twenty seconds. By this method, 2 ounces (60 cc.) of the 4 ounces ingested can be aspirated.

The aspirated contents are placed in sterile bottles, sent to the bacteriologic laboratory and worked up as soon as possible. Here the contents are centrifuged in 100 cc. tubes for forty-five minutes at a speed of 2,500 revolutions a minute. In most cases the sediment was rather scant and all, or the greater part of it, was used for animal inoculation. When there was enough sediment, part of it was treated with acid or alkali and cultured on cream and Lowenstein-Jensen medium.

19. Stadnichenko, A. M. S., and Cohen, S. J.: Read before the Mississippi Valley Medical Society in 1935.

20. Stadnichenko, A. M. S., and Cohen, S. J.: Gastric Lavage as a Means of Demonstrating Tubercle Bacilli in Pulmonary Tuberculosis, *Nat. Tuberc. A. Tr.* 33:125, 1937.

Since this work was more or less experimental and since there was doubt whether the acid-fast bacilli were tubercle bacilli, animal inoculations were made in all the thousand cases, regardless of the results with the smears. In the beginning of our work we used treated specimens for animal inoculation, but we observed in a few instances that while specimens showed typical acid-fast bacilli on the smears they failed to produce tuberculosis in animals. Repeated inoculations, however, with untreated specimens from the same patient gave positive results. This led us to the belief that some of the bacilli might be killed by treatment; therefore almost all the animals in this series were inoculated with untreated specimens. The mortality due to secondary infections among the guinea pigs inoculated with untreated specimens was less than 1 per cent, and most

of the deaths occurred in the summer, when the mortality in guinea pigs is always higher.

Several investigators have questioned the use of untreated sediment of stomach lavage. They state that most of their guinea pigs die of secondary infections. In checking our procedure we find that we inoculated the guinea pigs as soon as possible, usually within two hours after the stomach was aspirated. This short interval does not allow enough time for the growth of other types of bacteria. If more time is required, it is recommended that the specimen be kept in the ice box until it can be worked up.

Another important factor in preventing secondary infections and spontaneous tuberculosis in guinea pigs is to begin with healthy stock and to give good care after the animal is inoculated. This requires a skilled caretaker and a hygienic breeding house and animal hospital.

The guinea pigs were usually killed at the end of two months. Very few of these animals, even with extensive tuberculosis, died before this time. Smears

and cultures were made from the inguinal lymph nodes or spleen, or from both. The diagnosis of tuberculosis was never made on gross pathologic study alone—the acid-fast bacilli were always found on the smears before the animal was pronounced positive for the organisms.

This series of 1,000 cases might be divided into two main groups (excluding positive controls): a group in which tubercle bacilli were never found by routine examination and the stomach lavages were done to help establish the diagnosis, and a group used to guide therapy and to study its effect.

Most of the patients in this series (excluding controls with negative results) had rather scanty sputum, and that perhaps is one of the main reasons why it was difficult to find the sputum positive by direct or concentration examinations.

Poulsen and Anderson²¹ have shown that the percentage of positive results increases with the number of the repeated lavages. In their series of 199 tuberculous children (from 6 to 10 years of age) they obtained positive results with 152, or 77 per cent, on the first washing; but when the procedure was repeated three times the number of positive results increased to 193

(96 per cent), and after five washings they obtained 100 per cent positive results. Similar observations were made by Gullbring and Levin¹⁸ on their series of 348 adult patients, although the exact figures were not given.

The majority of the patients in our series had only one stomach lavage. Of 1,000 subjects 120 had two lavages and twenty had three. Of these 140 subjects, eight yielded positive results on the second lavage but not on the first, and two on the third and not on the first two. This increases the positive results by 7.3 per cent on repetition. In all our cases, however, from a few to many months had elapsed between the repeated lavages, so there is the possibility of a change in the condition of these particular patients.

We have divided the 1,000 patients into three main groups, with two subgroups and also positive and negative controls. The composite data of all patients are shown in tables 2 and 3.

GROUP 1

Group 1 comprised 249 patients. They had evidences of tuberculosis by x-ray or clinical study or by both. The results of sputum examination were always negative, but the results of stomach lavage were positive. Of these 249 patients, thirty-six became positive for bacilli on sputum examination later, necessitating the division of the group into two subgroups, A and B.

21. Poulsen, Valdemar, and Anderson, A. O.: Demonstration of Tubercle Bacilli and Significance in Prognosis, Therapy and Estimation of Danger of Infection, *Am. J. Dis. Child.* 47: 307 (Feb.) 1934.

Group 1 A was composed of 213 patients who were always negative for bacilli on routine sputum examination and remained negative but who by stomach lavage were found positive. Of these 213 subjects sixty-six (31 per cent) were found positive by smears; 211 were positive on guinea pig inoculations, while two were positive by stomach lavage culture but not by the guinea pig inoculation. These two cultures when inoculated into the guinea pigs proved to be virulent. Of the 211 patients who produced tuberculosis in guinea pigs, there was one with far advanced type B involvement whose direct smear of the stomach washing showed at least 10 acid-fast bacilli per field, yet the guinea pig showed only enlargement of the inguinal lymph nodes. The repeated stomach lavage in this case produced the same result, and even when a pure culture of the bacilli was injected into a guinea pig the only pathologic change observed was the enlargement of the inguinal lymph node. This was the only bacillary strain of low virulence encountered in the series.

There were three patients in this group who were absolutely insensitive to the Mantoux test. One patient had miliary tuberculosis, dying two days after leaving the Municipal Sanitarium. The condition of two other patients was diagnosed as far advanced tuberculosis. One was absolutely insensitive to the Mantoux test at the time the stomach washing was found positive, but the patient later had a strongly positive Mantoux reaction. The third patient was found positive for bacilli three different times on stomach lavage. The patient is having pneumothorax therapy, is feeling well, but is still absolutely insensitive to the Mantoux test. This involvement might belong to the Besnier-Boeck-Schaumann type. Only fifty-nine patients of this group were receiving collapse therapy.

There were twelve deaths (5.6 per cent) in this group, with three postmortem examinations.

As already mentioned, sixty-six patients in this group had positive smears yet their sputums were never found positive. Some of the smears of the stomach washings were very strongly positive, and it is rather difficult to explain why a patient having over eighty negative sputums should have 25 bacilli per field on stomach lavage. In some cases this may be explained on the basis of bronchial peristalsis which caused the bronchial secretions to go into the stomach without coughing, as suggested by Ulmar and Ornstein.¹² Most of these patients, when questioned, state that they either have no cough or raise practically nothing. The majority of sputum specimens in group 1 are nothing more than saliva. It is known that the introduction of pneumothorax therapy usually stops the cough and diminishes the expectoration. It is for these two groups of patients, therefore—those who do not cough and those receiving pneumothorax therapy—that stomach lavage is of greatest value, first in the diagnosis and second in the prognosis of the disease.

There were thirty-six patients in group 1 B. Their sputum was negative at the time when the results of stomach lavage were positive. Later on, however, the patients also were found positive for bacilli on routine sputum examination. The time that elapsed between obtaining the positive stomach washing and observing positive sputum varied from a few months to four and a half years in one case. The particular condition was of the minimal A type at the time the stomach washing was found positive. Now it is diagnosed as moderately advanced B with a positive sputum.

In this group, eighteen patients (50 per cent) were found positive on smear, and all thirty-six were positive on guinea pig inoculation. Twelve of them were receiving treatment other than routine. The mortality in this group was very high; there were eight (22 per cent) deaths with two postmortem examinations. Their pulmonary infections were of recent origin, as shown first by the negative sputums which finally became positive as the disease progressed, and second by the low age incidence associated with the high mortality. This group of patients, in spite of sanatorium care and collapse therapy, have the poorest prognosis. They no doubt include those with rapidly progressive involvement who, according to Bräuning's²² observations, comprise 20.9 per cent of all patients in the beginning of the disease. They represent the "sunrise" of the disease.

GROUP 2

In group 2 there were 253 patients. They not only had clinical and x-ray evidence of tuberculosis, but all of them, with the exception of twenty, once had positive

culous tracheobronchitis, bronchial catarrh or some other cause of the positive results. All of these features afford an excellent opportunity for a clinical-pathologic investigation as to the causes.

Group 2 B is composed of 159 patients of whom 139 had positive sputum and twenty had been found positive before by stomach lavage only. All 159 patients were negative on the last stomach lavage. Of this group, 110 received some form of collapse therapy. Only three patients of twenty who were found positive by stomach lavage and not by routine sputum examination received treatment at the time of the positive washing; but, when results of stomach lavage became negative, all but three were receiving collapse therapy. There were four deaths (2.5 per cent) in this group but no postmortem examination. These patients illustrate the value of collapse therapy in pulmonary tuberculosis in producing an absence of tubercle bacilli not only in the sputum but also in the stomach washings.

Groups 2 A and 2 B are being followed further to test the effect of therapy.

sputum. These twenty patients were previously found positive on stomach lavage, but they were never found positive on routine sputum examination. At the time the last stomach lavages were done on this group their sputum had been negative for at least nine months on routine examination. Of these 253 patients, ninety-four were found positive on stomach lavage, while 159 were negative even by this examination. We divided this group into subgroups A and B.

In group 2 A there were ninety-four patients whose sputum had once been positive but had been negative for at least nine months on routine examination before stomach washings were found positive. Of the ninety-four patients, forty-one (43 per cent) were found positive by smear, and all ninety-four were positive by guinea pig inoculation. Of these patients, fifty-three were having other treatment than routine. There were six deaths (6.5 per cent) with one postmortem examination.

This group showed that certain patients having collapse therapy have open lesions for long intervals even though the results of routine sputum examination are negative. Many may have had small lesions on the contralateral side, only partial collapse, ulcerative tuber-

GROUP 3

Group 3 is made up of 262 patients whose condition was diagnosed as pulmonary tuberculosis by clinical or x-ray examination, or both; yet their sputum has always been negative and also their stomach washings. It is to be regretted that only forty-two of this group had repeated lavages. As Poulsen⁴ and others have pointed out, repeated lavages increase the percentages markedly. Had we repeated the stomach lavages on all 262 patients we might have found some of them positive. Yet this is not the principal cause of the negative results. One reason is that seventy-nine patients received collapse therapy; another reason is that there was a high percentage of minimal and moderately advanced lesions. In these cases of minimal tuberculosis the diagnosis was made either from a history of two or three symptoms such as fever, cough, hemorrhage, loss of weight or pleurisy or from some small shadows on the x-ray plate.

Perhaps the most interesting cause for the negative results in this particular group is that it contained a high percentage of patients in whom the disease had apparently run its course and had become spontaneously arrested or healed, otherwise known as the "good chronics." That is, there was a predominance of patients

22. Bräuning, Hermann: Der Beginn der Lungentuberkulose beim Erwachsenen. Leipzig, Georg Thieme, 1938.

belonging to clinical class A. This is indicated by the marked shift from the young adult to the patient of middle or old age in this group, as revealed in the chart.

In twenty-eight cases the diagnosis was pleurisy with effusion; in ten of them pleural fluid was found positive, in four it was negative and in fourteen it was not examined. The fourteen patients entered the Municipal Sanitarium after practically all their pleural fluid had been absorbed.

There were three deaths (1.1 per cent) in this group, but no postmortem examinations. One death occurred in the group of patients who had pleurisy with effusion; one patient had silicotuberculosis, and the third had far advanced fibroid involvement.

POSITIVE CONTROLS

A statement has been made that patients with frankly positive sputum are usually negative by stomach lavage, but we were not able to confirm it. We tried stomach lavage on from thirty to forty positive patients, and every one was positive by this test. These frankly posi-

postmortem examinations: sixteen had lung cancers (with nine autopsies and four biopsies, which confirmed the diagnoses for thirteen); eleven had lung abscess with one postmortem examination; seven had syphilis; five had gland tuberculosis; four had bronchial asthma; three had Hodgkin's disease (the diagnosis was confirmed by two autopsies and one biopsy); three had cardiac disorders; three had nontuberculous empyema; two had tuberculosis of the spine; two had nontuberculous pleurisy with effusion, and one each had bronchitis, chronic sinusitis, pneumoconiosis, idiopathic spontaneous pneumothorax, tuberculous peritonitis and carcinoma of the breast. There were seventeen in this group who died (10.4 per cent), and postmortem examinations were made on all of them. The autopsies confirmed the absence of pulmonary tuberculosis. There were eighteen patients absolutely insensitive to the Mantoux test, five reacted to the 1 to 10 dilution, and six reacted to the 1 to 100 dilution.

COMMENT

The value of stomach lavage for adults as well as for children has greatly exceeded our expectations. Perhaps the most gratifying result is the discovery that acid-fast bacilli in the stomach content are virulent and not indifferent saprophytes. Another equally important observation is that in nontuberculous conditions acid-fast bacilli are found rarely, if at all. These two facts taken together at once rule out saprophytic acid-fast bacilli and possible accidental tubercle bacilli that may be found in the mouth and stomach.

In order to support this view we aspirated the stomachs of six healthy scrub women in the Municipal Sanitarium who we thought had been markedly exposed to the tubercle bacillus. All these women showed an absence of tubercle bacilli in the stomach contents. In other words, the first observation establishes the fact that positive stomach washings indicate an endogenous origin of tubercle bacilli in the stomach region or above it. The second fact establishes proof that there is no open focus discharging tubercle bacilli and that the particular patient either is not tuberculous or has a lesion which is enclosed, arrested, or closed by treatment. All of this information is of tremendous importance in the diagnosis and differential diagnosis of tuberculosis and in the control of treatment. Stomach lavage may be called the "court of last appeal" in finding tubercle bacilli in the respiratory and upper gastrointestinal systems. This applies equally well to adults and to children. It emphasizes also the fact, pointed out by Ulmar and Ornstein,²² that sometimes tubercle bacilli pass out of the bronchi by peristaltic waves into the esophagus without cough and without contaminating the saliva sufficiently to cause a positive reaction. Finally, it is the best method to obtain certified specimens of sputum in suspected fraud.

The first two groups represent the net profit of the method. In all, 249 patients were found positive on stomach lavage when up to that time no other test had established the diagnosis. Of this number thirty-six later became positive according to other tests, but that was perhaps due to a further evolution of the disease after the time of the analysis. Most involvements were recent or in the sunrise stage of the disease. Of 940 patients negative on direct examination, 249 (26.5 per cent) were never found positive by any other method than stomach lavage. Taking out the positive and negative controls and the subjects who were once positive leaves a total of 511 patients on

tive patients, however, are not included in this group. Our positive control group consisted of sixty patients, fifty of whom were found positive by sputum only once, with from one to ten organisms per slide; the other ten patients were found positive twice. Of these sixty subjects thirty-six (60 per cent) were found positive by smear, while all sixty were positive by animal inoculation.

It is interesting to note that in a number of cases the sputum showed only one organism per slide but the smears from the stomach washings showed more than ten per field. Stomach lavages were usually done shortly after the sputums were found positive.

Only twenty-one patients in this group received treatment other than routine. There were eight deaths (13.3 per cent) with seven postmortem examinations.

NEGATIVE CONTROLS

In this group there were 176 patients. They were under observation. The sputums were always negative and the stomach washings were also negative. Of the 176 subjects, fifty-two had a normal x-ray appearance and no clinical evidences of tuberculosis or any other disease at the time of examination, while thirty-seven had calcified tubercles. These were discharged as not having any active tuberculosis. The condition of twenty-five was diagnosed as bronchiectasis, with four

whom to base percentage figures. This gives an efficiency value of 48.7 per cent for the type of material presented in this report.

In group 2 there were 253 patients once positive but negative for nine months or more on the routine sputum examination at the time stomach lavages were done. Out of these 253 subjects ninety-four (group 2 A) were found still positive by the lavage method, while 159 (group 2 B) remained negative even by lavage. In group 2 A fifty-three patients were under collapse therapy, and in group 2 B 110 were receiving this treatment.

In group 3 there were 262 patients negative on all examinations. The analysis of this group is very interesting. There were seventy-nine who received pneumothorax, which could very well account for the persistently negative observations. There were sixty-eight with minimal involvement in which the disease presumably did not advance far enough to discharge bacilli in the main bronchi. Twenty-eight had a diagnosis of pleurisy, ten of whom were positive, but the sputums were always negative. One had cold miliary tuberculosis, three had silicotuberculosis, and seven apparently had a healing type of adult primary lesion. The remaining seventy-six patients had lesions which had healed partly or entirely so that only stringy apical fibrosis or an old closed fibroid process with emphysema remained. They were in the "sundown" stage of the disease. Many such patients pass over into the negative group with bronchiectatic abscess or emphysema, some of which fail even on postmortem examination to show the tuberculous origin. Of this group fifty-four were over 30, thirty-five over 40 and eighteen over 50 years of age. Many no doubt had had the disease for decades.

In the group of negative controls there were 176 subjects. There were twenty-five cases of bronchiectasis, in most of which the disease may have been of nonspecific origin, but in some it may have been old "sterilized" tuberculosis. There were sixteen cases of lung cancer, in most of which autopsy or biopsies were performed. The eleven lung abscesses were more likely nonspecific. In the fifty-two "normal" cases there were some ephemeral processes causing the patient to be sent to the Municipal Sanitarium, but nothing could be found on clinical, x-ray or laboratory examination. In thirty-seven cases rather large calcified primary lesions were the only evidence of disease at the time of the examination made after entry to the institution. The remainder of the cases are well shown in table 3.

SUMMARY

1. A study was made of 1,000 consecutive patients who were given stomach lavage in the Municipal Tuberculosis Sanitarium, 970 of whom were over 10 years of age. Of this group, 940 were negative for tubercle bacilli by the routine concentration method, fifty were positive only once, with from one to ten bacilli per slide, and ten were positive only twice at the time stomach lavages were done.

2. The sixty patients just mentioned were found positive by stomach lavage and were used as positive controls. There was no point, however, in reporting cases strongly positive.

3. There were 176 negative controls whose clinical and x-ray aspect pointed definitely to a normal status at the time of examination or to diseases other than lung tuberculosis. All were negative on stomach lavage.

4. There were 253 patients who had been positive but were negative for nine months or longer, by routine

examination, before the stomach lavage was performed. Of these, ninety-four were positive by stomach lavage and 159 remained negative.

5. Of the remaining 511 patients always negative by routine methods, 249 (48.7 per cent) were positive by the stomach lavage method alone.

6. Of the remaining 262 patients always negative, seventy had early minimal or moderately advanced involvement; seventy-nine received pneumothorax therapy; twenty-eight had pleural effusions, and seventy had terminal fibroid lesions where infiltrative foci had disappeared and only stringy fibrosis or fibroid cavities remained. This left only twelve patients to be divided up among a number of complications or unusual features.

7. Of 403 with stomach washings positive by guinea pig inoculation, 161 (40 per cent) were positive by smear.

8. Of 824 patients with pulmonary tuberculosis, 334 had some form of collapse therapy, which has been present from two months to several years. Of these 334 patients, seventy-nine (23.7 per cent) were never permitted to become positive and 110 (32.9 per cent) became negative by stomach lavage, while 145 (43.7 per cent) were still positive by stomach wash.

9. In this study of 1,000 cases we did not include any unusual observations or make any comparison between the efficiency of the stomach wash and that of the sputum culture. We have such a comparison under investigation at the present time.

CONCLUSIONS

1. Stomach lavage will find tubercle bacilli that become free in the larger bronchi in a manner not equaled by any other method used at present.

2. The patients having tuberculosis who are not found positive for tubercle bacilli by stomach lavage include those with early minimal or moderately advanced lesions which have remained isolated or have been confined to the pulmonary parenchyma or otherwise have not disseminated bacilli into the larger bronchi; completely encapsulated lesions, and extrapulmonary tuberculosis, none of which discharge bacilli into the bronchi or pharynx.

3. Completely healed tuberculous lesions and non-tuberculous diseases are uniformly negative by stomach lavages.

4. As stomach lavage seems to come nearer than any other method to finding all virulent tubercle bacilli, it should be adopted as the ultimate standard for absolute negativity or apparent cure of patients having had or suspected of having tuberculosis. It is also useful in the elimination of frauds.

5. While it is not practical or even necessary for universal use, the efficiency of any method used or recommended for practical use may well be standardized by it.

6. It is an excellent method to control the efficiency of collapse therapy.

7. It should be emphasized again that during collapse therapy the absence of tubercle bacilli in only one stomach washing does not necessarily signify that the disease is arrested. The washings must be repeated at frequent intervals. Especially is this true when the collapsed lung is reexpanding.

8. No patient with clinical signs of tuberculosis who has negative sputum should be considered negative until gastric aspiration has yielded negative results.

DIAGNOSTIC VALUE OF OCCULT
HEMATURIAA STUDY OF 3,000 SPECIMENS OF URINARY
SEDIMENT

JOSEPH H. BARACH, M.D.

AND

L. LEWIS PENNOCK, M.D.

PITTSBURGH

This article is based on an investigation concerning the meaning and clinical implications of occult blood in the urine. To this end we examined 3,000 specimens of urine obtained from 681 ambulatory patients. The group, in the main, was made up of patients with cardiac, vascular, circulatory, renal, nutritional and other nonacute types of diseases. It did not include gross hematuria such as occurs in from 40 to 60 per cent of patients whose disorders are finally diagnosed as surgical conditions of the genito-urinary tract.

THE TOLIDINE TEST

A small amount of blood or hemoglobin is best detected by the orthotolidine test, which is sensitive up to 1 part of blood in 24,000 parts of urine. One

drop of blood in 1,500 cc., an average daily output, will give a positive reaction. For clinical purposes this chemical method of detecting blood in the urine is more accurate than the usual microscopic search for red blood cells; it yields a greater number of positive results. Its interpretation, however, must be tempered with clinical judgment. While the presence of a positive occult blood reaction indicates bleeding somewhere along the urogenital tract and nothing else, one must interpret its clinical significance in the light of medical experience.

The orthotolidine test has been used to detect blood since its introduction by Ruttan and Hardisty in 1912.¹ Stone and Burke² in 1934 observed that (1) when red blood cells are present in the urine a positive tolidine reaction will be found, (2) that red blood cells in the urine are not ordinarily detected with the microscope until their number exceeds 5,000 per cubic centimeter of urine, and (3) that persistent observation of more than 1,000 red blood cells per cubic centimeter is of clinical significance and merits further consideration.

Read before the Allegheny County Medical Society, Pittsburgh, April 18, 1939.

1. Ruttan, R. F., and Hardisty, R. H. M.: *Canad. M. A. J.* 2: 995, 1912.
2. Stone, W. J., and Burke, G. T.: *Improved Test for Occult Blood, Especially in Urine*, J. A. M. A. 102: 1549 (May 12) 1934.

It need hardly be emphasized that the detection of even small amounts of blood in the urine is desirable in clinical work at all times.

Our observations cover a period of four and one half years, during which time we have had ample opportunity to note the frequency and intensity of the reaction with various disease states. We found it convenient and sufficiently accurate to classify the reactions as grade 1, 2 and 3. As outlined by Stone and Burke and verified by ourselves, grade 1 (1 plus) corresponds to from 1,300 to 1,500 red blood cells per cubic centimeter of urine, 2 plus corresponds to from 4,000 to 7,000 red blood cells per cubic centimeter, and 3 plus corresponds to from 15,000 to 20,000 red blood cells per cubic centimeter.

In performing the test, 15 cc. of urine is centrifuged at high speed for five minutes. After the supernatant liquid has been decanted and discarded, part of the sediment is used for the usual microscopic examination. To the remainder of the sediment in the centrifuge tube is added 2 drops of 1 per cent solution of orthotolidine in methyl alcohol, followed by 4 drops of acetic acid-hydrogen peroxide mixture (glacial acetic acid 1 part and commercial hydrogen peroxide 2 parts). Positive reactions consist of a greenish blue lasting one minute (1 plus), a deeper blue lasting up to two minutes (2 plus) and a deep blue lasting more than two minutes (3 plus). Strong alkalis, as 10 per cent sodium hydroxide, will give a positive reaction, but the common organic or inorganic urinary constituents do not. Iodides or bromides in the urine will give a falsely positive reaction, consisting of a deep bluish black with precipitation of black granules. Excess ascorbic acid in the urine, as during tests or administration of vitamin C, will inhibit the orthotolidine reaction and prevent its appearance.

INCIDENCE

Of 3,000 specimens taken from a group of 681 general medical patients, we found that 33 per cent showed positive tolidine reactions. At the same time we also found that 67 per cent of these 3,000 specimens showed positive reactions for albumin in the urine. These figures clearly indicate that occult blood in the urine, as revealed by the presence of hemoglobin, is one thing and that serum albumin as it occurs in the urine is another. If this incidence of hemoglobin and albumin seems high, it should be recalled that we are dealing here with patients who have recognized diseases and those in whom circulatory disturbances in the renal glomeruli or mucous membrane of the genito-urinary tract are to be expected.

AGE AND SEX

To gain an insight into the meaning of the presence of occult blood in the urine we segregated a group of 100 younger patients up to the age of 20, consisting of forty-eight males and fifty-two females. In this group of 100 we found that one third gave positive tolidine reactions. We also noted that in this group of young patients showing traces of blood in the urine the sexes were evenly divided, with twenty-seven males to twenty-six females. As will be seen later, occult bleeding is somewhat less common in young than in older patients.

Influence of sex on the presence of occult hematuria (table 1) is as follows: The group of patients with positive tolidine reactions consisted of 40 per cent males and 60 per cent females. The excess of females over males is probably to be accounted for by a greater source of bleeding in the female, the generative tract.

SEASONAL INFLUENCE

Since these observations covered a period of four and one half years, we were interested in the possibility of seasonal variations, with their contrasting temperatures, the changes in activity of the circulatory system and the various physiologic responses which may come in the course of a year. The accompanying chart shows however that seasonal factors are not constant, although our highest incidence occurred during the height of the summer.

RELATION OF POSITIVE TOLIDINE REACTION
TO ALBUMINURIA

The entire group of 681 patients had 3,000 tests for detection of occult blood, averaging more than three tests per patient, although some had many more and the others less. Of these, 24 per cent of the positive reactions were in males and 42 per cent in females. It is noteworthy that of the 3,000 specimens 67 per cent also showed albumin in the urine. This, of course, includes a large proportion of samples showing mild albuminuria which was not an indication of existing nephritis. Further analysis revealed that 63 per cent of the males and 71 per cent of the females in the entire group showed albuminuria.

While this incidence of occult blood and albumin seems high, it must be recalled that we are dealing here with patients seeking medical aid for well defined diseases. That both the incidence of occult blood and the incidence of albumin were higher in the female than in the male is to be explained on the basis of the more extensive areas of mucous membrane in the generative tract of the female.

ABNORMAL DEXTROSE METABOLISM AND OCCULT
BLOOD IN THE URINE

The questions arose as to whether occult blood in the urine is more common in patients having hyperglycemia and glycosuria and as to whether the diabetic state per se may cause direct injury to the smaller blood vessels and capillaries with resulting bleeding. In an analysis of the data for 100 diabetic patients during

does not have any immediate injurious effects on the renal glomeruli as far as blood or capillary injury is concerned.

HYDROGEN ION CONCENTRATION AND THE
TOLIDINE TEST

The tolidine reaction was neither more nor less marked in acid or alkaline urine. Most of the specimens ranged in hydrogen ion concentration between

Seasonal influence on occult hematuria (3,000 specimens of urine, 1934-1938).

6 and 8, which is within the normal range (table 2). Thus it appears that the hydrogen ion concentration of the urine is not a factor and has no influence on the tolidine test.

BLOOD COUNTS AND OCCULT HEMATURIA

The next question that presented itself was whether such occult bleeding in the genito-urinary tract may be one of the underlying causes of secondary anemia, so frequently seen in this type of patient, or whether the fault resides in defective blood regeneration or other causes. We therefore correlated a group of 154 patients whose urinalyses revealed a 3 plus tolidine reaction, which means a continuous loss of from 15,000 to 20,000 red blood cells per cubic centimeter of urine. In this analysis we found first that the red blood cell values are not strikingly lower than for any other mixed group of patients and second that the hemoglobin level was relatively lower than the red cell value, which suggests definite hypochromia.

OCCULT HEMATURIA IN VARIOUS DISEASES

Of the 681 patients, groups with various diseases are classified according to the degree of anemia (table 3). All of these had 3 plus tolidine reactions, which means well marked occult blood in the urine. It will be seen that severe secondary anemia, diabetes with active cardiovascular renal disease, pure cardiovascular renal disease, chronic nephritis and uncomplicated diabetes appear in this table in their positions of relative severity. It is also apparent that the relative positions in this table correspond with our clinical conceptions of the seriousness of these diseases. How much the occult bleeding is responsible for the anemia present in these cases is not an easy matter to decide.

OCCULT HEMATURIA IN SERIOUS DISEASES

The clinical significance of a positive tolidine reaction and its value as an index of serious disease may be inferred from our observations on a group of 662 patients with various diseases. Subdivided into disease

TABLE 3.—Occult Hematuria in Various Diseases

No. of Cases	Disease	Red Blood Cell Average, Million	Hemo-globin Average, %	Tolidine Reaction
6	Severe anemia.....	3.78	36.0	+++
11	Diabetes and cardiovascular renal disease.....	4.43	77.4	+++
25	Cardiovascular renal disease.....	4.53	77.4	+++
9	Chronic nephritis.....	4.60	76.5	+++
62	Miscellaneous diseases.....	4.64	79.7	+++
41	Diabetes, uncomplicated.....	4.83	81.0	+++

periods of hyperglycemia and glycosuria we found that there actually was a lower incidence of occult blood during these periods. As far as these observations go, we have no evidences indicating that the diabetic state of the patient is accompanied by immediate capillary injury or occult bleeding.

ADMINISTRATION OF ARSPHENAMINE AND
OCCULT HEMATURIA

Of a group of seventy patients who received intravenous injections of arsphenamine, we note that whereas 30 per cent had positive tolidine reactions before the injections only 20 per cent had positive reactions after the injections. It therefore appears that this arsenical

groups, 375 patients showed an incidence of positive tolidine reactions in from 50 to 89 per cent of the cases. Table 4 shows this incidence and the type of disease in which the highest percentage of occult blood was found in the urine. Thus we note that foremost in this list was a group of diabetic patients with recognized cardiovascular disease. After this was chronic nephritis; then came genito-urinary diseases, then cardiovascular renal diseases including cardiac and hypertensive states with or without nephritis. These were followed by pernicious anemia, tuberculosis, asthma, arthritis and other conditions.

All of this tends to show that the presence of a positive tolidine reaction in the urine is significant. In the absence of a diagnosable constitutional disease it may only mean unimportant occult bleeding somewhere along the urinary tract. But in the presence of one of the constitutional diseases it is more likely to serve as an index of the extent to which that disease involves the renal glomeruli or smaller blood vessels or capillaries. In a disease such as diabetes with cardiovascular disease, only 11 per cent of the patients did not show occult bleeding; in chronic nephritis all but 12 per cent had occult bleeding. In pure cardiovascular renal diseases, including essential hypertension and other conditions, 37 per cent had negative reactions, whereas

TABLE 4.—Various Diseases and the Tolidine Reaction

8	Tuberculosis.....	50
8	Renal glycosuria.....	50
6	Asthma.....	50
4	Arthritis.....	50

in uncomplicated diabetes 42 per cent had negative reactions. Thus positive occult blood reactions have their well defined clinical meanings, and absence of occult hematuria takes on a prognostic significance in the order of first importance. A negative occult blood reaction gives one assurance of intact vessels in the urogenital tract, which is one of the most important systems in the human organism.

SUMMARY AND CONCLUSIONS

Orthotolidine is a sensitive test for occult hematuria. A positive orthotolidine reaction was found in one third of 681 general medical cases of the so-called chronic diseases. It is less common in youth, with more intact vessels, and it is more common in females than in males on account of the greater source of bleeding in the female generative tract. Seasonal variation pointed to the highest incidence during the summer months. Albuminuria and occult blood are found independently of each other, each having its own significance. Glycosuria is not a cause of occult bleeding. Arsenicals in therapeutic doses do not cause occult bleeding. Alkalinity or acidity of the urine is not a cause of occult bleeding. In patients showing persistent occult hematuria, hypochromic anemia is common. A review of the type of case in which the strongest reactions occurred reveals that these reactions were most pronounced in the clinically recognized serious types of disease and that the test reflects the patient's actual condition.

The terms "food poisoning" and "ptomaine poisoning" are frequently used in the diagnosis of an acute illness characterized by vomiting, cramps, diarrhea and elevation of temperature. Both terms are unsatisfactory, but, of the two, "ptomaine poisoning" is the more misleading and incorrect, for actual food poisoning rarely if ever occurs. Since vomiting is often the first symptom, it is perhaps natural that suspicion should be directed to the food eaten and vomited.

Investigators in food poisoning have suggested various classifications; none have been found satisfactory unless they are based on etiology. In general, food poisoning is classified in two groups: infection and toxemia. Food infection is the result of contamination of food with various types of living bacteria. Food toxemia is due to the ingestion of food which contains preformed bacterial toxins; botulism is the example in this class.

Rosenau¹ says: "Most instances of food poisoning are from food that is fingered and fussed over, inadequately processed or imperfectly preserved. There is little danger in fresh, clean food, whereas food that is prepared hours before it is eaten gives opportunity for the growth of bacteria. The chief offenders in food infection are meat, milk and mixtures containing these products."

Food infection is an acute disease, usually associated with one of the *Salmonella* group, although streptococcus and staphylococcus outbreaks have been reported. The symptoms of food infection are those of acute gastrointestinal irritation with nausea, vomiting, diarrhea, prostration, dehydration and a rise of temperature to 102 F. or even higher. The severity of the symptoms varies according to the strain of the organism and the dose. The onset is sudden; usually from six to fifteen hours elapses from the time the food is eaten to the beginning of the first symptoms, although cases have been reported in which the illness began immediately on ingestion of the infected food.

Numerous epidemics of food poisoning have been reported in this country and abroad. Gartner in 1888 did much to clear the mystery concerning food poisoning when he reported a *Salmonella enteritidis* outbreak in Frankenhansen. Fifty-seven cases occurred with one death, and it was determined that the disease was due to eating meat of a cow which was slaughtered on account of enteritis. The infecting organisms were recovered from the organs of both the cow and the patient who died. Owing to the fact that greater pre-

Dr. Brown was formerly secretary and executive officer, Kansas State Board of Health.

cautions are now exercised in the processing and preparation of food, these infections occur less frequently than in the past.

Bainbridge reported at least 261 outbreaks in Germany between 1898 and 1908 due to infection with either *Salmonella suipestifer* or *Salmonella enteritidis*,

Geiger² surveyed 749 outbreaks in this country which occurred from 1910 to 1922 inclusive and involved 5,210 persons with 399 deaths. Forty-four outbreaks were due to botulinus infection with 172 cases and 140 deaths; fifty-four outbreaks, with 2,219 cases and eleven deaths, were due to the eating of food contaminated with organisms of the paratyphoid group. In 404 outbreaks the diagnosis was given as ptomaine poisoning by physicians, and in 147 additional outbreaks this was the diagnosis according to newspapers carrying reports of the occurrences. In 212 outbreaks the assembled data indicated conditions other than food poisoning.

Savage³ tabulated 112 British outbreaks of bacterial origin from 1878 to 1918, and 121 from 1919 to 1931 inclusive. In the latter series seventy-six, or 63 per cent, were due to infection with *Salmonella aertrycke*, fourteen, or 12 per cent, to *S. enteritidis* and seven, or 6 per cent, to *S. suipestifer*.

Lecoq in Paris published in 1906 a monograph on poisoning caused by whipped cream. He showed that the poisoning properties of mixtures of cream, gelatin and white of eggs had long been known but that the poisonous properties which appeared most frequently in the summer were due not to metallic poisons but to bacterial infection of the egg albumin. The method of infection which he thought most likely was the introduction of infective material into the oviduct of the duck during copulation, with infection of the albumin as it was being deposited around the yolk. Lecoq recited numerous observations of foreign bodies such as straws, seeds and stones found embedded in eggs and obviously introduced in this manner. The greater frequency of infection of duck's eggs was explained by the fact that ducks "practice their amours" in ponds and ditches, where specific contamination of the water may easily be present.

Scott⁴ in 1930 reported seven British outbreaks in which duck's eggs were the vehicle of infection. The largest outbreak in this series involved more than 300 persons with one death, the vehicle being ice cream. Although proof was not entirely complete it appeared that a duck's egg infected with *Salmonella aertrycke* and used in the manufacture of the ice cream was responsible. The ice cream contained an abundance of *S. aertrycke*, while none of the other ingredients of the mixture except the eggs could be suspected.

Scott also directed attention to another method of infection of the eggs. Eggs of both ducks and hens, if kept dipped in cultures of *S. aertrycke*, may become infected in a few days. If the culture is simply allowed to dry on, infection fails; part of the shell must remain moistened for penetration to occur.

Authorities are agreed that the diagnosis of food infection depends on the following general principles: (1) history of exposure to the suspected food, (2) symptoms suggestive of food poisoning, (3) isolation of the infecting bacteria from the suspected food and also

from the blood, urine, feces or viscera of the patient, (4) specific identification of the causative organism, and (5) demonstration of agglutinins in the blood serum of the patients.

Numerous outbreaks of food infection have been reported in medical literature in this country; reports of *S. aertrycke* infection are rare. It is desired, therefore, to report an outbreak of fifty-two cases in which *S. aertrycke* was the active cause and was transmitted by food.

One of us (G. R. C.) for many years had been attending physician to an orphanage for boys and girls of ages ranging from 5 to 17 years. The building occupied by the boys is more than half a mile distant from that occupied by the girls, although the two are operated by the same religious order. The milk supply, produced at the boys' home, is shared with the girls' home. The water supply for each is secured from the municipal system. Sewage disposal at the home for boys is by means of a septic tank, and the effluent drains into a small creek 150 yards distant.

On the morning of May 27, 1936, we were notified by telephone that a large number of the boys were ill. The call was answered promptly and it was discovered that, in addition to development of a sudden illness among the boys, several adult attendants also were ill. The symptoms were those of an acute infection with sudden onset, nausea and vomiting, fever, severe diarrhea (many had bloody stools) and extreme prostration. Temperatures varied from approximately 100 to 106 F. The patient with the latter reading was removed to the hospital, and the illness resulted fatally.

In the first case illness developed at about 1 o'clock on the morning of May 26, and in two other cases the onset occurred between that hour and 5 o'clock. In the great majority of cases onset took place between the latter hour and 6 o'clock of that evening, with an interval of approximately thirteen hours.

We immediately suspected a food-borne epidemic. Illness had not occurred at the girls' home, and therefore water and milk were not involved. The meal which was eaten at 6 o'clock on the evening of May 25 consisted of chopped fried beef, boiled potatoes, mustard greens, bread and butter, milk and rice custard pudding.

A telephone report of the occurrence of the outbreak was made to the state department of health. Representatives of this department arrived five hours later to continue the investigation.

The boys as well as the adult attendants were housed in two brick buildings, both being exceptionally clean. Flush water closets in the two buildings were in satisfactory condition. There were four frost-proof toilets in an outbuilding, approximately 35 yards from the main building. These toilets were in disrepair, although showing evidence of recent use.

The meals were prepared and served in the main building. Screening on the windows and doors of both kitchen and dining room was defective. Flies were found in large numbers in both of these rooms.

Of the various foods which were eaten, rice custard pudding was the most likely vehicle of infection. The rice was boiled during the early morning and allowed to stand on the table for several hours. The custard was prepared during midafternoon, mixed with the rice and then allowed to stand for an unknown length of time before being placed in the refrigerator. In making the custard, among other ingredients, four

4. Scott, W. M.: *Brit. M. J.* 2: 56 (July 12) 1930.

duck eggs and two hen eggs were used. Since those who had prepared the custard were also ill, they could not have been the primary source of the infection.

Approximately 1 pint of the rice pudding remained in the refrigerator. On laboratory examination, *S. aertrycke* was isolated from the pudding and also from the stools of seventeen patients, one of whom died.

The fifty-two patients were distributed by age groups as follows: from 5 to 9 years, fifteen; from 10 to 14 years, twenty-two; from 15 to 19 years, six, and over 21 years, nine. Included in the adult group were two men and seven women, each having a part in the management of the home or of the small farm which supplied potatoes and other vegetables. Seven adults and twelve boys were not ill, having eaten the pudding either not at all or in only a small amount. In some cases this was reported as a "taste" or a spoonful.

All patients were exceedingly toxic, the apparent result of a massive dose of the infection. It was not considered that flies could be responsible because the time elapsing between preparing and eating the pudding was not sufficient to allow for incubation of the organisms. Therefore the investigation was directed to the possibility of infection resulting from the use of duck eggs in preparation of the pudding.

Cultures were made from eighteen freshly laid eggs within twenty-four hours from the time they were laid, without recovering the organism.⁵ Cultures were taken from the outside of four eggs, and *S. aertrycke* was recovered from two.

Certain experimental work was then undertaken. Two eggs were placed in a Petri dish in which filter paper was moistened with sterile water. A third egg was washed and wrapped in filter paper moistened with broth culture of *S. aertrycke* isolated from the custard, and a fourth egg was inoculated by hypodermic syringe with a similar culture, the hole being sealed with paraffin. One egg, used as a control, was placed in a sterile Petri dish without other attention. All eggs were allowed to stand at room temperature for one week. At the end of this period the eggs were broken and cultures were made from them. The control egg was negative for organisms, but *S. aertrycke* was recovered from the other eggs. This indicated that under certain conditions the organism would penetrate the shell.

Ducks lay their eggs in a casual manner, dropping them wherever they may be feeding. Duck eggs are usually dirty when gathered, and if they remain on the ground for several days it is possible that the organism will penetrate the shell. If the infection is in the oviduct, the organism may enter the egg during its development.

There were twenty-one ducks on the property; the eggs were used only for cooking. These fowl had the run of the small farm, which was fenced, including the creek. Fecal specimens were secured from all of the ducks. *S. enteritidis* was isolated from nine specimens, *S. aertrycke* from six and both organisms from three, while three were reported negative for both organisms. *S. aertrycke* and *S. enteritidis* were also isolated from the septic tank effluent where it entered the stream.

Blood specimens were then secured from the nine ducks whose feces had been positive for *S. aertrycke*. Ordinarily, blood is taken from fowls by inserting a

needle into the humeral vein beneath the wing. This method was attempted, but only a few drops could be obtained before the blood coagulated in the needle. The following method was then used: The ducks were held by the wings with the body and feet hanging down. A foot was cleaned with alcohol, one of the large veins in the web was punctured, and the blood was allowed to drip into sterile tubes. By using this method, a sufficient sample was easily obtained from each of the ducks.

The blood of three ducks agglutinated the organism isolated from the custard and from the stools of various patients. These ducks were purchased but did not lay any eggs after they were brought to the laboratory. At the end of fourteen days they were killed, autopsies were performed, and cultures were taken from the oviduct of each. *S. aertrycke* was recovered from one on direct culture and from the second on enrichment. Cultures from the third duck were negative.

In a further investigation of the possible source of the infection, it was learned that the man in charge of the farm became sick on May 21. His symptoms were similar to those of the others who were ill. Although he had severe diarrhea, he continued his work and defecated frequently on the floor of a shed adjacent to the barn, to which shed the ducks had free access. *S. aertrycke* was recovered from the stools of this man more than two weeks after the onset of his illness.

This farmer lived in his own home approximately a mile from the orphanage. His wife had not been ill and her stools were negative for *S. aertrycke*. He did not eat at the orphanage or handle any of the food and denied having used the toilets. The source of his infection was not determined.

Rice custard was the vehicle of infection in this outbreak. Duck eggs which were used in preparation of the pudding were, without doubt, responsible for contamination of the pudding. Infection of the eggs could have occurred during their development in the oviduct, or organisms could have penetrated the shell if a period of several days intervened between the time the eggs were laid and were collected.

SUMMARY

1. An outbreak of *Salmonella aertrycke* infection occurred in an orphanage for boys.
2. Of the fifty-five boys and sixteen adults living in the orphanage, forty-three boys and nine adults were sick. One death occurred.
3. All persons who were ill had eaten rice custard pudding.
4. Onset of the first case occurred approximately seven hours after ingestion of the suspected food.
5. *S. aertrycke* was isolated from the pudding and from the stools of seventeen patients, including the one who died.
6. *S. aertrycke*, either singly or in combination with *Salmonella enteritidis*, was recovered from the feces of nine ducks. The blood of three ducks agglutinated the organism recovered from the pudding as well as the organism isolated from the stools of various patients. On autopsy, *S. aertrycke* was recovered from the oviduct of two ducks.
7. The infection was transmitted in rice pudding. The infecting organisms were contained in the duck eggs used in making the pudding, in sufficient quantities to result in massive infection of the custard.

5. The laboratory work was done by Ross L. Laybourn, M.S., bacteriologist in charge, Public Health Laboratory, Kansas State Board of Health, since deceased. References to such work in this paper are taken from his notes.

TEMPORAL ARTERITIS

GEORGE F. DICK, M.D.

AND

GUSTAVE FREEMAN, M.D.

CHICAGO

Horton and Magath¹ reported eight cases of temporal arteritis in 1937. Five of these they had studied personally. One of the cases occurred in Uruguay. The same year MacDonald and Moser² reported a case and compared the disease with periarteritis nodosa. Jennings³ reported two cases from England in 1938 and discussed the similarity of temporal arteritis to periarteritis nodosa, thrombo-angiitis obliterans and rheumatic arteritis. Two more cases are described here.

There is a striking similarity clinically and pathologically among all the cases that have been described in detail. The range in age has been between 55 and 80 years, the average being 67. Six of the thirteen patients were between 65 and 70. More women than men have been affected. Weakness and general malaise prior to and during the local involvement of the arteries about the head were common. The prodromal symptoms varied in duration from two weeks to eight months, although it is not clear whether the contiguous signs and symptoms are related to this disease. In some instances the disease dated from an infection of the respiratory tract and was followed by muscle and joint pains. All the patients had headaches. These were often throbbing in nature and associated with tenderness of the scalp and painful mastication. The swelling and redness of the periarterial tissues usually followed the onset of headache. Fever was invariably present during the height of the disease, generally remaining below 103 F. In several instances impairment of vision resulted from damage to the retinal vessels. Muscular weakness was pronounced in our second case. It seems usual for the patient to discover tender swelling over the temporal arteries or behind the ears or to feel pain around an eye. In several instances one side of the face swelled and became tender, followed by a similar series of events on the other side. Tender swellings appeared frequently over the entire scalp. In one case even the buccal cavity became swollen and tender. Jennings described involvement of the arteries in an arm. Horton and Magath reported that the disease lasted from four to six months, but one of our patients was sick for thirteen months. Thus far the disease has always been incapacitating. Despite the advanced age distribution, none of the patients died of the disease.

Investigation of the pathologic changes is limited to the small number of excised portions of temporal arteries. Only ophthalmologic examination has thrown light on the picture of the disease process in the smaller arteries. The portions of temporal arteries removed were relatively firm and rigid. Their lumens were narrow and sometimes completely occluded (fig. 1). The walls were markedly thickened. Microscopically the media and adventitia were profusely invaded by

mononuclear inflammatory cells (figs. 2 and 3). In places the musculature was replaced by masses of granulomatous inflammatory tissue. Occasionally hemorrhages appeared in the media. Proliferation of the intima was considerable but not specifically different from that seen in arteriosclerosis, although atheromatous material was not commonly seen. The elastic laminae were usually obliterated. The most characteristic elements of the inflammatory reaction in the arteries were the large giant cells. These were scattered throughout the media in conjunction with the inflamed areas. These cells were quite large and contained many nuclei. Sometimes they were poorly preserved and appeared to be compressed. It has not been possible to demonstrate organisms in the tissues by bacterial stains. No specific cellular aggregations were found constituting tubercles, gummas or Aschoff bodies. The lumens were greatly reduced in width and thrombi occasionally obliterated them entirely.

REPORT OF CASES

CASE 1.—A woman aged 65 had been living in Illinois all her life. At 29 she was jaundiced and had vomiting attacks. At 63 she had influenza. She has been able to distinguish only light and dark with her right eye. In December 1937 she had an attack of influenza which lasted three weeks. This attack was accompanied by fever and a bloody mucopurulent discharge from the nose. Immediately on recovery the patient noted pain and tenderness behind each ear. This persisted for three weeks.

She was well until May 1938, when bronchopneumonia developed, lasting five weeks. During the middle of June the left eye became swollen and painful. This condition subsided in a few days but the right side of the face became swollen, tender and firm. Even the roof of the mouth was involved. A week prior to admission to the hospital the left side of the face and neck became affected similarly. Pain was prominent in the jaws and mouth. Cordlike swellings were felt along the occiput, behind the ears and over the temples.

The patient was acutely ill and undernourished. Subcutaneous swellings were felt in the regions of the occipital, posterior

2. MacDonald, J. A., and Moser, R. H.: Periarteritis and Arteritis of Temporal Vessels: Case Report, *Ann. Int. Med.* 10:1721 (May) 1937.

3. Jennings, G. H.: Arteritis of Temporal Arteries, *Lancet* 1:424 (Feb. 19) 1938.

auricular, parietal and middle temporal arteries. The middle temporal and supra-orbital arteries felt like firm cords except for the pulsation. The retinal veins appeared engorged. A mucoid discharge came from the nose. The teeth were carious and broken. The temporomandibular joints were painful and limited in motion. The submaxillary, anterior and posterior cervical lymph nodes were enlarged and tender. A systolic murmur was heard over the entire precordium. The second pulmonic sound was louder than the second aortic. The radial and brachial arteries were thick. A few small mucosal hemorrhages were seen on the palate.

The patient was hospitalized for seven and one half weeks. The temperature usually had an afternoon peak of 100 F. After a total of 13.2 Gm. of sulfanilamide was administered

Fig. 2 (case 1).—Inflammatory reaction including giant cell in media. Reduced from a photomicrograph with a magnification of 1,050 diameters. (Hematoxylin-eosin stain.)

over a period of seven days the temperature rose to 100.4 F. and then returned almost to normal the following day. The drug was stopped when a rash appeared. Sulfanilamide was given again for two days with a consequent rise in temperature and a rapid return to normal. While the patient was in bed, vision in the left eye became blurred. The optic disk was twice normal size and was slightly edematous. A small hemorrhage was present on the disk. The visual field was reduced to a small point. A biopsy was made of the right middle temporal artery.

The urine and stools were essentially normal. The leukocyte count ranged between 6,300 and 13,100 cells per cubic millimeter. The differential counts were not unusual. The hemoglobin varied from 70 to 78 per cent. The erythrocyte count ranged between 4,500,000 and 4,900,000 cells per cubic millimeter.

Reactions to the Wassermann and Kahn tests were negative. Hemolytic streptococci were revealed by cultures of material

taken from the throat. A blood culture showed no growth. *Streptococcus viridans* grew in a culture made from the temporal artery.

The patient was feeling well in September.

CASE 2.—A woman aged 76, who had come to Chicago from Sweden fifty years before, had frequent sore throats all her life. In 1918 she had influenza. Four years later the gallbladder was removed. In 1928 she had acute tonsillitis. In 1936 her right knee became swollen and tender.

In November 1937 the patient began to have severe frontal headaches. The aching included the eyes and the face as far down as the lower jaw. These headaches persisted until June 1938. In April 1938 tender swelling of the left temporal artery appeared. Then the right side became involved. Soreness of the eyes and blurred vision followed. There was diplopia for one week. Her muscles were sore and the joints felt stiff. Examination in June revealed large, firm, tortuous pulsating temporal arteries, tenderness of the scalp, tortuous retinal arteries, sluggish extra-ocular movements, poor vision in the right eye, inflamed tonsils, adenitis, enlarged cervical lymphnodes and a blood pressure of 172 systolic, 80 diastolic. Between June and October the headaches were absent but the patient did not improve otherwise. In October the temporal arteries looked the same. Examination revealed warm and moist skin, enlarged anterior cervical lymph nodes, small tender swellings over the occiput and small cysts on the surfaces of the tonsils.

The patient was hospitalized for twenty-three days. She had constant night sweats. The muscle soreness and stiffness in the joints improved. The temperature ranged from 99.2 F. to 100.4 F. daily. Sulfanilamide was administered for eight days without effect. There was an occasional trace of albumin and a moderate number of white cells in the urine. The red cell count was 3,350,000 per cubic millimeter and there was 10.3 Gm. of hemoglobin. The blood count became normal with iron therapy. The Wassermann and Kahn reactions were negative. The sedimentation rate and cell volume were normal. The urea clearance was moderately reduced. The blood urea was 18 mg. per hundred cubic centimeters of blood. No free acid was obtained from the stomach after histamine. X-ray examination of the skull was negative. There was marked widening of the innominate artery, according to the film, and the sinuses were clear. An electrocardiogram showed a tendency toward left axis deviation.

It was not until two months later that the vascular signs subsided.

COMMENT

Jennings questioned the specificity of the syndrome and compared it with periarteritis nodosa, rheumatic arteritis and thrombo-angiitis obliterans. Nevertheless he points out more differences than similarities and by description strengthens the view that temporal arteritis is not the same disease as any one of the others. The characteristics they have in common are fever, sweating, loss of weight, anemia, muscle and joint pains, periarteritis, medial inflammatory reactions with hemorrhages, intimal proliferation and thrombosis. The clinical symptoms are those of inflammatory involvement of blood vessels. Pathogenically the changes in common are those expected in chronic inflammation of arteries regardless of etiology. The several clinical entities are obscure etiologically but are considered to be separate diseases according to our present state of knowledge by virtue of clear clinical differences. For similar reasons temporal arteritis should be isolated at present as an individual entity.

The pathologic material obtained is insufficient to give a satisfactory picture of the disease. The important differential element in the inflammatory process is the invariable presence of large giant cells in the walls of the arteries. No aneurysms have been noted on biopsy of the temporal arteries. The giant cells have not been associated with other cellular elements to form

specific tubercles or gummas. Giant cells have not been associated with thrombo-angiitis obliterans, rheumatic arteritis or polyarteritis nodosa.

It has been suggested that the etiology may be related to degenerative vascular changes occurring commonly in persons in this age group. The invariable presence of fever and inflammation and the self-limiting course of the disease point to the process of infection. An infection superimposed on arteriosclerosis may enhance the severity of the disease by permitting the occurrence of thrombosis more readily. Thus far bacteriologic investigation of removed portions of arteries has revealed nothing striking. In two instances *Streptococcus viridans* was recovered from the arteries.

Fig. 3 (case 11).—Inflammatory reaction including giant cells in media. Reduced from a photomicrograph with a magnification of 1,050 diameters. (Mettaxoxilin-eosin stain.)

Some of the patients had infections of the respiratory tract preceding the vascular disease. The muscle and joint symptoms suggest that the disease may include a much wider distribution of tissues than the blood vessels of the head.

SUMMARY

Two cases of temporal arteritis are added to the eleven previously reported in the literature. The disease is a chronic inflammatory process involving the temporal arteries mainly with extension to other arteries of the scalp and face and sometimes to the retinas and the arms. It is a disease occurring chiefly in old people. It runs a self-limiting course, lasting usually several months. Giant cells are found characteristically as part of the inflammatory process. The etiology is unknown.

"SLOW EPINEPHRINE"

AN EXPERIENCE

FREDERIC G. DORWART, M.D.

MUSKOGEE, OKLA.

Since the advent of protamine zinc insulin several years ago, efforts have been increased, I believe, toward the preparation of drugs which would be, when injected subcutaneously or intramuscularly, like protamine zinc insulin, piecemeal in action, slow in action, safer in action, and more efficient in action because of these qualities. Thus, no doubt, when Keeney¹ published his preliminary report in 1938 on a "Slowly Absorbed Epinephrine Preparation" interest became more centered on epinephrine than before. Then a year later the same author² gave in detail his experiences with epinephrine in oil in twenty-four cases. The epinephrine in oil he used was a suspension of powdered epinephrine base in peanut oil, 1 cc. of the oil containing 2 mg. of epinephrine, or a 1:500 mixture. Ten patients who had had asthma, chronic in its manifestations, received relief from their symptoms of asthma for from eight to sixteen hours, while one patient received no prolonged effect from the doses that were indicated. Eleven others were treated during one or more acute paroxysms of asthma, remaining free from asthma for from nine to sixteen hours; one patient with urticaria and one patient with serum sickness secured evident relief from their symptoms for twelve hours. In comment as to the ill effects experienced from the drug, Keeney states that there may or may not be soreness, induration and swelling, with redness, at the points of injection and that frequent and consecutive injections may be irritating in the same fashion. However, the drug can be injected intramuscularly without producing a local reaction.

In one case, fifteen minutes after the administration of epinephrine in oil there was experienced palpitation and nervousness which endured for forty-five minutes; in another, headache, palpitation and nervousness of such a degree was produced that the drug was used no further; in a third case, within five minutes after the injection of epinephrine in oil, nervousness, palpitation and irregular cardiac action came on and lasted for sixty minutes. Because of the rapidity with which this picture was brought about it was thought that a part of the material, at least a part, had entered some small blood vessels during the injection.

Spain, Strauss and Fuchs³ have more recently reported on "A Slowly Absorbed Gelatin-Epinephrine Mixture," a 1:500 gelatin-epinephrine mixture used in fifty cases, deducing from the study of these that the 1:500 gelatin-epinephrine mixture was slowly absorbed, was nontoxic, and from its use marked clinical improvement often results; and also that there is a reduction in the number of doses required when the gelatin-epinephrine mixture is substituted for the regular solution of epinephrine. In one case this slow epinephrine produced an unbearable amount of nervousness, insomnia and later headaches, necessitating the discontinuance of the drug.

1. Keeney, E. L.: Slowly Absorbed Epinephrine Preparation: Preliminary Report, *Bull. Johns Hopkins Hosp.* 62: 227-229 (March) 1938.

2. Keeney, E. L.; Pierce, J. A. and Gay, I. N.: Epinephrine in Oil: New, Slowly Absorbed Epinephrine Preparation, *Arch. Int. Med.* 62: 119-142 (Jan.) 1939.

3. Spain, W. C.; Strauss, M. B., and Fuchs, A. M.: A Slowly Absorbed Gelatin-Epinephrine Mixture, *J. Allergy* 10: 209-214 (March) 1929.

The descriptive literature of epinephrine in oil states that this is a suspension of 2 mg. of powdered epinephrine crystals in 1 cc. of peanut oil and that the dose in adults is from 0.75 to 1.5 cc. to be given intramuscularly. Also that patients who are in need of epinephrine because of an acute paroxysm of asthma had best be given the selected dose of the 1:1,000 aqueous solution of epinephrine hydrochloride subcutaneously, followed with the indicated intramuscular injection of epinephrine in oil. It cautions against a larger dose than 1.5 cc. for adults and that it should not be given to the aged or to patients who have hypertension and the like.

REPORT OF CASE

Mrs. W. L. C., white, aged 22, a housewife, when seven months pregnant in the early part of 1938 experienced her first attack of asthma, which however lasted only twenty-four hours and responded for from two to three hours at a time to 2 to 3 minims (about 0.15 cc.) of the 1:1,000 aqueous solution of epinephrine hydrochloride. Soon after her baby was born at full term (this baby being now alive and well) she had her second attack, which lasted only two or three hours and required just two injections of epinephrine of from 2 to 3 minims each for relief.

June 4, 1939, or thereabouts she had her third attack of asthma, then again June 10 another attack, which lasted all night and was so severe by 11 o'clock the morning of June 11 that she called for help, and then she was given 5 minims (0.3 cc.) of epinephrine and 1 cc. of slow epinephrine in the right deltoid muscle. From this she quickly received relief from her wheezing and the asthmatic breathing but soon became extremely nervous, restless and shaking, with the feeling as if she were going to die. This continued on and increased in severity until I saw her at 11:35 a. m. That she was responding quite intensely to epinephrine was most evident for she had a deep pallor, she was restless and there were fibrillary twitchings of the muscles generally, especially of the arms and the upper part of the legs. Her expression was one of great fear. The respiratory rate was 30, the pulse rate irregular, at times not felt, counted around 160, but her heart tones were not booming and were not prominent. In fact, it was difficult beneath the rapid breathing rate to hear the heart tones clearly. In the abdomen, which was quite thin, an abdominal pulse was seen and easily palpated. At the moment it was not quite clear as to why this picture should have resulted from epinephrine unless she had been given a huge dose; she had been given, as stated, 5 minims of epinephrine subcutaneously and 1 cc. of slow epinephrine intramuscularly. The patient was lying in her bed at home, for she had not the strength to sit up or move about, and she had the feeling that if she were to move she would collapse.

Since the picture presented an emergency, I pulled loose one of the rubber tubes of a stethoscope and used it as a tourniquet above the belly of the right deltoid muscle, back of the area in which the epinephrine in oil had been injected, and we held this tourniquet tight. Within a minute or two the patient ceased her restlessness and the twitchings of the muscles were over with; the pulse rate decreased none in count, however, but became more regular and better felt. Likewise, the abdominal pulse was not so apparent. She was relaxed now and smiled. Then when it was felt that the tourniquet had been in place a time, lest it might cause damage to the arm or the fingers, it was released, and within a half minute there returned the restlessness, nervousness, twitchings, the irregularity of pulse and there was a deepening of the pallor and the appearance of anxiety. At the moment when I determined that the patient had had enough of this, I again used the tourniquet and the response was as before: a quieter patient, a better pulse, a lessening of the pallor.

The tourniquet was kept on for a while and off for a while until it seemed advisable to take her to the hospital, for I did not know how long it would take to get rid of the epinephrine in oil, and I knew that at the hospital there were measures that could be used to bring about a quicker recovery from this

trying experience. I accompanied the patient, therefore, to the hospital in an ambulance, holding the tourniquet in place and reaching the hospital at 12:20 p. m., where it was once again noted on release of the tourniquet at the moment when the fingers were becoming numb, perhaps hurting a little, that within a minute the muscular twitchings, restlessness, nervousness, pallor, anxiety and irregularity of pulse rate had all returned. When the patient had all she could stand of this, the tourniquet was reapplied, securing fairly quickly a calmer individual. At 12:27 a capsule of pentobarbital sodium was given and at 12:30 an intravenous injection of 5 per cent dextrose in saline solution was begun. At 12:50, in the midst of the epinephrine effect, the blood pressure was 110 systolic, 60 diastolic and the pulse rate irregular, from 140 to 150. At 12:53, after the tourniquet had been in place about two minutes, the pulse rate was 152 and the heart tones were normal except for the rapid rate. There was cyanosis generally, especially of the lips, fingernails and the palms of the hands. On the right arm where the tourniquet was being applied, and immediately on release of the tourniquet, the blood pressure was 100 systolic, 54 diastolic. Gradually, with the tourniquet being kept on for a while and off for a while, and with the effect of the pentobarbital sodium apparently coming into play, the patient closed her eyes and became somewhat drowsy. The epinephrine reaction became somewhat less severe, so that by 1:30 the tourniquet was taken off and left off. By 3:25 the pulse rate had dropped down to 120 and the respiratory rate to 20, the pallor had in marked degree disappeared and there were no contractions of the muscles. The patient at this hour was discharged; she walked out.

The next day, June 12, the patient's husband called on the telephone stating that his wife had supper the night before and slept all night, though at 1 o'clock in the morning she took a capsule of pentobarbital sodium. She was able to eat breakfast in the morning.

COMMENT

The question What has happened here? of course arises. The picture is one of responses, severe in manifestations, to epinephrine. Can a small blood vessel in a muscle be broken open by a needle or ruptured by oil dispersion and remain open for two hours so that it can take up the drug that is in its area? I doubt that this is true. Has the epinephrine base separated out of the oil and been pooled and thence absorbed in huge quantities and more quickly, and has water (in a wet syringe) or tissue juices (muscle) had anything to do with such effect? I'd rather think that the patient's tolerance to epinephrine was low. She is a thin, healthy looking person, not very tall, and has no stigmas of thyrotoxicosis.

Every effort has been made to describe this case without exaggeration. Because of the anxieties and fears, because of the unusual responses and the severity of responses, and because the patient was in a home, the case was truly one of emergency.

CONCLUSIONS

1. Slow epinephrine (epinephrine base in peanut oil) has been used in an acute paroxysm of asthma.
2. The severest of responses to overdosage of epinephrine resulted.
3. All cautions should be followed in the use of slow epinephrine.

Still Seeking Truths.—Today, truths are still being sought out on the same lines as those which Harvey gave us. It would be a mistake to think that we have, even yet, reached a point that approaches finality in medicine, in surgery, or, indeed, in any of the sciences.—Robarts, H. H.: *If Health be Wanting*, Edinburgh M. J. 46:725 (Nov.) 1939.

EPINEPHRINE HYDROCHLORIDE IN
ACUTE PUERPERAL INVER-
SION OF UTERUS

REPORT OF THREE CASES

AUGUST F. DARO, M.D.

BYFORD F. HESKETT, M.D.

AND

HERBERT A. SCHILLER, M.D.

CHICAGO

Inversion of the uterus has been so well covered in the literature and standard textbooks on obstetrics and gynecology, particularly those by Curtis,¹ Irving,² Cooke,³ Williams,⁴ Graves⁵ and De Lee,⁶ that we shall attempt here only a brief summary of existing thought with special reference to management of acute puerperal cases. More particularly, we shall consider the use of epinephrine hydrochloride as an aid in reduction of the uterus to its normal position and report three additional cases in which this treatment was used.

Epinephrine hydrochloride has been particularly useful in prolonged labor with contraction ring as reported by Weiss,⁷ Rudolph and Ivy⁸ and others. The experimental and clinical work with the drug and studies on the physiology of uterine contraction by Rucker,⁹ Rudolph and Ivy,¹⁰ Rudolph¹¹ and Ivy, Hartman and Koff¹² are of great interest. De Lee¹³ expressed doubt whether this drug will relieve uterine spasm. The consensus indicates that epinephrine hydrochloride relaxes the uterine muscle, usually after one contraction, even in the presence of solution of posterior pituitary or ergotamine tartrate.

Having used this drug successfully many times with contraction rings, at the suggestion of Dr. J. E. Fitzgerald, of our staff, we decided on its use in acute inversion of the uterus as reported by Urner,¹⁴ hoping that the cervix would relax enough to make replacement of the corpus possible. In cases of inversion of the uterus, epinephrine has been used for treatment of the accompanying shock, we feel in insufficient doses to relax the uterus adequately. Its use in the treatment of shock probably precedes attempts to replace the uterus by too long an interval to be efficacious.

Inversion of the uterus is a relatively rare condition in which the uterus is turned inside out. The incidence varies considerably, being approximately one case in from 100,000 to 113,000 pregnancies, according to Findley's¹⁵ and Curtis's¹ reviews of the literature,

respectively. Irving² reported one case in 7,837 deliveries at Boston Lying-in Hospital and Maxwell¹⁶ one case in 6,500 deliveries at the University of California Hospital. Jacobs¹⁷ reported not a single occurrence in 250,000 cases at the St. Petersburg Lying-in Hospital, while Findley¹⁵ reported only one inversion in 280,000 cases at the Vienna Lying-in Hospital. Davis¹⁸ and others expressed the belief that it is occurring more frequently since the advent of solution of posterior pituitary. Curtis¹ stated that the incidence is roughly one case in 6,000 deliveries and that the regrettable circumstances surrounding some cases may account for their failure to appear in the literature. Kobak,¹⁹ in going over the Chicago Department of Health records, found seven deaths due to inversion of the uterus in 94,000 deliveries over a two year period; in five of the seven cases the condition was diagnosed at autopsy, being unrecognized before death. These, of course, were only autopsy statistics and do not include acute cases with survival, so that the condition is probably much more common than is generally recognized.

Inversion of the uterus may be classified in various ways. It may be puerperal or nonpuerperal, depending on whether it occurs incidentally to delivery or in conjunction with pedunculated submucous tumors. It may be complete or incomplete, depending on whether the fundus has passed through or is within the cervical ring; the complete variety is the most common in the literature, but many writers suggest that this may be true because incomplete inversion goes unrecognized. According to Cooke³ inversion may be spontaneous or traumatic, depending on etiology. According to Kellogg's²⁰ classification, it may be acute, subacute or chronic, the acute type having not over forty-eight hours' duration with a relaxed cervical ring, the subacute type having under thirty days' duration but with definite cervical constriction, and the chronic type being present for more than thirty days.

The cause is still unknown, although many theories have been advanced. Cooke³ stated that the traumatic variety is the most common and blamed traction on the cord with the uterus relaxed and improper attempts at placental expression. This view has also been held by Gordon,²¹ Milne,²² Browne²³ and others. Findley¹⁵ stated that no amount of force applied from above could invert a well contracted uterus and that the cord would rupture before traction from below would invert it. Irving² concluded from his review of the literature that probably in most cases inversion is spontaneous. According to Murphy,²⁴ Dudley²⁵ and Ashton,²⁶ the uterine musculature beneath the placenta is relaxed while the placenta is still intact; owing to the weight of the placenta the uterus becomes indented, and therefore with contraction of the surrounding muscle there is an attempt to expel it. Uterine inversion seems to be more commonly reported in primiparas, and in primiparas the placenta is a little more likely to be implanted in the

fundus, according to Beckmann,²⁷ Vogel,²⁸ McCullagh²⁹ and Zangemeister,³⁰ although it is certainly not due to this fact in all cases because Holmes³¹ reported four cases and Thorn³² two cases in which it was a complication of placenta praevia. Irving² stated that the nonpuerperal type such as is produced by submucous fibroids is usually incomplete. Curtis¹ stated the opinion that the relaxed uterine supports usually present in these cases may have something to do with the etiology.

The pathologic condition is simply that the uterus is turned inside out; because of this the bladder, tubes and ovaries and ligaments are drawn down into the crater with marked traction on the ligaments. Some authors, notably Jolly³³ and Curtis,¹ have concluded that this is the cause of the profound shock, which is often out of all proportion to the amount of hemorrhage.

The symptoms and clinical picture are usually those of shock, with hemorrhage, possibly some pain, a tumor mass in the vagina or presenting at the vulva, and absence of the uterus from its usual position. The constricted cervical ring causes congestion with venous bleeding. There should be no trouble in making a diagnosis if the condition is kept in mind, although according to reports in the literature some appalling things have been done.

If there is disagreement in the literature as to the etiology of this condition, there seems to be almost uniform agreement as to the immediate treatment in acute cases. Curtis,¹ Irving,² Cooke,³ Williams⁴ and others have all urged that nothing radical be done before the shock is treated and that no attempt to replace the uterus be made until the patient is in better condition, except to place the uterus in the vagina and pack and apply a pad with pressure to help control hemorrhage. McCullagh²⁹ found that 30 per cent of the patients died when early attempts at replacement were made in the presence of shock and only 5 per cent when the shock was treated first. Irving² stated that this is proof enough, and Curtis¹ said that "it is dangerous to proceed when shock is present."

At this point in the treatment the road divides, and there is a diversity of opinion as to the best method of replacing the uterus. Cooke³ advised attempts at replacement with the patient under morphine or an anesthetic. He warned against use of solution of posterior pituitary, as it may make reduction difficult owing to the hardness of the uterus and after replacement it may initiate reinversion. He stated that if the uterus cannot be replaced it should probably be removed. Curtis¹ said that Huntington, Irving, Kellogg and Masson favor abdominal replacement. In our opinion there is no doubt that operative correction or hysterectomy is the procedure of choice in chronic cases; we feel that our efforts have been so successful that the treatment is certainly worth a trial in acute puerperal inversion.

REPORT OF CASES

CASE 1.—A white secundipara aged 24 entered the Cook County Hospital at 2 a. m. in the service of one of us (A. F. D.)

in extreme shock, practically moribund and bleeding vaginally. The nurse's note on admission will give some idea of her desperate condition: "Pulse imperceptible, color blanched, air hunger, skin cold and clammy, pads saturated with blood, packing loose, patient restless but unresponsive, pupils dilated and oval." The resident's note stated that "on admission the patient was gasping, pulseless, ashen gray and cold, blood pressure was impossible to register." The note sent to the hospital with the patient by the physician who attended her during her confinement stated that she had "postnatal hemorrhage with a fibroid tumor of the uterus." The history of the delivery was obtained from the husband. The baby was born at home six hours before the patient's admission to the hospital. After a short wait the physician attempted a manual removal of the placenta. The afterbirth was attached to a tumor, from which it was peeled; the tumor was replaced. The patient continued to bleed; a prescription for fluidextract of ergot was left and the physician departed. Because the bleeding continued after several doses of the medicine, the physician was called back; he sent the patient to the hospital after packing the vagina.

On admission to the hospital, intravenous administration of 1,000 cc. of 2.5 per cent dextrose and 0.4 per cent saline solution was started immediately; because of the extremely precarious condition of the patient 500 cc. of group IV citrated blood was given intravenously from the blood bank with 500 cc. of 0.9 per cent saline solution, without cross matching. Shock therapy was instituted with administration of heat, 10 minims (0.6 cc.) of a 1:1,000 solution of epinephrine hydrochloride, 7½ grains (0.5 Gm.) of caffeine with sodium benzoate and another 1,000 cc. of 5 per cent dextrose given intravenously.

After two hours the patient began to rally, and the resident examined her because of marked bleeding through the pack. The pack was removed and the uterus found to be inverted and about 1 cm. within the introitus. There was considerable bleeding from many vessels over the entire surface of the uterus. The cervix was firm and tightly drawn over the inverted uterus. A gentle attempt at reduction failed, and it was thought inadvisable to do more until the patient was in better condition. The vagina was packed tightly; one-fourth grain (0.015 Gm.) of morphine sulfate was given and this medication repeated one and one-half hours later for restlessness. A second and a third intravenous injection of 500 cc. of citrated blood, each diluted with 500 cc. of 0.9 per cent saline solution, were given after cross matching was done, and another dose of 7½ grains of caffeine with sodium benzoate. At this time the pulse rate was 76 and the temperature 96.4 F.

About eight hours after admission to the hospital and about fourteen hours after delivery, after three transfusions and administration of 3,500 cc. of fluid, the patient was in fairly good condition. Ether anesthesia was started and the patient was prepared for vaginal examination. Fifteen minims (1 cc.) of a 1:1,000 solution of epinephrine hydrochloride was given; the fundus relaxed but the cervix remained tight, so the same amount of epinephrine was given in eight minutes. At this point relaxation of the cervix occurred with softening of the uterus. Reduction of the inverted uterus was easily accomplished. With the hand in the uterus, the operator (A. F. D.) could feel attempts of the organ to reinvert, so one ampule of ergonovine malate was given and another in seven minutes, after which an intra-uterine pack was placed. In about one hour and forty-five minutes the patient was awake and talking to her sister, in good condition and with a pulse rate of 108. The next morning the temperature had risen to 100.4 F. and the pulse rate to 92. After an ampule of solution of posterior pituitary had been given, the pack was slowly withdrawn and the posterior pituitary medication repeated. Administration of ergonovine malate ½ grain (0.0002 Gm.) three times a day and of sulfanilamide 15 grains four times daily was started because of the temperature. The red blood cell count after the third transfusion was 3,240,000 and the white cell count 27,700. After a fourth transfusion, the red cell count was 3,750,000. Because of moderate cyanosis, the sulfanilamide was discontinued. The temperature went as high as 102 F. and a foul lochia was present, but the patient was able to be discharged from the hospital on the fifteenth postpartum day.

About two weeks later she again was admitted because of vaginal bleeding and an upper respiratory infection. The temperature remained normal except for one reading of 99.4 F. Pelvic examination at this time showed that the cervix was soft and admitted one finger; the fundus was enlarged and seemed to have a greater transverse than longitudinal diameter.

CASE 2.—A private patient was seen in consultation by Dr. James Bloomfield,³⁴ one of the attending physicians at County Hospital. She was in shock, four hours after the inversion occurred and after the placenta had been peeled off. She was receiving intravenously physiologic solution of sodium chloride and a transfusion had just been started. Fifteen minims of a 1:1,000 solution of epinephrine hydrochloride was given, and this was repeated in fifteen minutes. Without any anesthetic and in the presence of shock the uterus and cervix relaxed and the fundus was easily replaced and packed. The patient was given tablets of ergonovine malate, $\frac{1}{320}$ grain three times a day for three days. After twenty-four hours part of the pack was removed, and in thirty-six hours the remainder was removed. Ten minutes after the uterus was replaced the patient, who had been in profound shock (the physician who called Dr. Bloomfield told him he didn't think she would be alive by the time he could get there), was sitting up talking to her friends. From his experience Dr. Bloomfield thinks that this method should be tried immediately, even in the presence of shock; if not successful, the shock should be treated and some operative procedure performed.

CASE 3.—A white secundipara aged 24, admitted to Cook County Hospital in the service of Dr. Alfred Kobak, had been sent to the antepartum clinic of the hospital by her private doctor because of high blood pressure and albumin in the urine, but she had had no toxic symptoms. Although, according to the menstrual date, delivery was due two days after she was seen in the clinic, the examining physician there thought she was only seven months pregnant. A rectal examination disclosed the head at the spines; after this the patient passed about an ounce of bright red blood without pain. She was sent into the hospital, where a sterile vaginal examination was made. No placenta was felt and the membranes were intact.

Two days later she went into labor and after five hours delivered her baby spontaneously. Ten minutes later the uterus had risen high up in the abdomen, the lower uterine segment was soft and the fundus was firm. The patient was instructed to bear down with pressure applied to the abdomen with the flat of the hand. The cord advanced and finally the placenta appeared at the vulva. Moderate pressure was exerted over the fundus and the placenta was expelled, but the membranes were adherent. The basin containing the placenta was gently moved up and down and the placenta-like tissue advanced. Because the placenta seemed large, an inversion was suspected and the resident was called. He confirmed the diagnosis. There was an accompanying hemorrhage of between 800 and 1,000 cc. The placenta had almost completely separated from the fundus at this time and the patient had gone into shock. No active bleeding followed the inversion. Shock therapy was instituted. External heat and $7\frac{1}{2}$ grains of caffeine with sodium benzoate were administered, and 1,000 cc. of physiologic solution of sodium chloride and 300 cc. of acacia solution (30 Gm. of acacia in 100 cc. of distilled water diluted with physiologic solution of sodium chloride to 300 cc.) were given intravenously until blood could be obtained. In the presence of shock, 10 minims of a 1:1,000 solution of epinephrine hydrochloride was given and the uterus was easily replaced after removal of the placenta. One ampule of solution of posterior pituitary and one ampule of ergonovine malate were given, and because the uterus contracted well only a vaginal pack was placed. A tear extending to the rectal mucosa was sutured. The first transfusion started caused a slight reaction and so was discontinued, but the patient was later given 1,000 cc. of citrated blood from the blood bank diluted with 1,000 cc. of physiologic solution of sodium chloride intravenously, and one fourth grain of morphine sulfate and $\frac{1}{320}$ grain of ergonovine malate every four hours for six doses. The patient's admission temperature was 99 F., pulse rate 96 and blood pressure 148 systolic, 94 diastolic. Seven hours post

partum the temperature was 101.6 F. and the pulse rate 152, but from that time the temperature rapidly fell to normal, although the pulse rate remained between 84 and 100. The patient was discharged on the eighth postpartum day in good condition. She had no foul lochia. The placenta was attached in the fundus.

COMMENT

After reviewing these three cases, we were all impressed by the ease with which reduction of the uterus was accomplished after the use of adequate doses of epinephrine hydrochloride, and we feel that 15 minim doses should be used and repeated if necessary.

In spite of the fact that these patients usually come out of shock soon after replacement of the uterus, one must still face the fact presented in the literature that six times as many die when treated during the shock. We are in complete accord with Dr. Bloomfield that if inversion should occur to one of our patients in labor we would immediately try replacement with the use of epinephrine hydrochloride; but we feel that, as most of these patients are brought into the hospital in shock, the shock probably should be treated first.

We feel that inversions of the uterus are real emergencies and that the help of every one in the service who can be spared is essential to good treatment. First morphine sulfate in one fourth or one half grain doses should be given, and then because a patient in shock is likely to have collapsed veins the intravenous fluids should be started, followed by transfusion as soon as suitable blood can be obtained. Next the patient should be kept warm and given stimulants, and the foot of the bed should be raised. The uterus should be placed in the vagina and the vagina packed to prevent hemorrhage as far as possible. The placenta should not be removed until replacement is attempted because this increases the blood loss. Enough blood and intravenous fluid, either physiologic solution of sodium chloride or 5 per cent dextrose, should be given to build up the patient's blood pressure. After the patient's condition is considered suitable, she should be prepared and draped on the table. The first 15 minim dose of a 1:1,000 solution of epinephrine hydrochloride should be given, then the placenta should be peeled off and, if the uterus and cervix relax, replacement attempted. If the uterus and cervix do not relax, the same amount of epinephrine should be given; we feel that, if this is done, attempts at replacement will usually meet with success.

We realize that it is very hazardous to transfuse without cross matching, but it was deemed necessary in the first case by those who were present.

Inversion of the uterus, particularly the acute puerperal type, is a formidable complication of labor. It may be spontaneous or may be induced by improper management of the third stage of labor. Because traction on the cord and improper attempts at expulsion of the placenta are common and the condition relatively uncommon, one wonders if this procedure is as important an etiologic factor as the literature would lead one to believe. The ease with which the fundus slipped through the cervix, particularly in the first case handled by one of us (A. F. D.), makes us wonder if this may not point to the cause, namely an unusually relaxed cervix and fundus. Inversion produces bleeding and profound shock usually out of proportion to the bleeding. If shock is present, the consensus is that it should be treated before attempts at replacement of the uterus are made. In the three cases presented epinephrine hydrochloride in adequate doses seemed to facilitate easy replacement of the uterus.

34. Bloomfield, James: Personal communication to the authors.

CONCLUSIONS

1. Acute inversion of the uterus is a rather rare but serious complication of labor.
2. If inversion occurs, it can probably be corrected immediately, before shock occurs, by adequate doses of epinephrine hydrochloride.
3. If shock is present, the shock should be treated before replacement is attempted.
4. Replacement is facilitated by adequate doses of epinephrine hydrochloride, namely 15 minims, repeated if necessary.

Clinical Notes, Suggestions and New Instruments

DEATH FROM AIR EMBOLISM FOLLOWING PERIRENAL INSUFFLATION

HENRY M. WEYRAUCH JR., M.D., SAN FRANCISCO

The incidence of air embolism is not high, but it is a potential danger whenever air is injected into any organ or tissue of the body. The increasing popularity of perirenal insufflation as an aid in the diagnosis of tumors of the retroperitoneum makes pertinent a note of warning concerning the method.

The literature abounds with clinical reports of death from gas embolism following the introduction of air or oxygen into the urethra, bladder, uterus, pleura, peritoneum or blood stream. It would be paradoxical to assume that the retroperitoneal space is endowed with an invulnerability which these other structures do not enjoy. I cite a case from my own experience to attest the fact that this region is subject to the same hazard.

A white woman aged 38 entered the hospital complaining of a swelling in her right flank of four months' duration. On physical examination a smooth, extremely hard mass was palpated in the right upper quadrant of the abdomen. It moved with respiration and seemed to occupy the region of the right kidney, which could not be felt apart from it.

A bilateral pyelo-ureterogram (fig. 1) showed a normal left upper urinary tract. The right kidney was displaced downward and medially, the upper portion of the ureter coursing in front of the fourth and fifth lumbar vertebrae.

On the basis of the abdominal examination and pyelographic studies a clinical diagnosis of retroperitoneal tumor was considered likely. In order to be more certain of the location of the mass, however, it was decided to perform a perirenal insufflation. This procedure was carried out in the manner described by Cahill.¹ A blunt spinal puncture needle was introduced below the midpoint of the rather long twelfth rib and advanced until the usual "jump" was felt as the end pierced the transversalis fascia. Following removal of the stylet no blood escaped from the needle and none could be aspirated when a syringe was attached. With the aid of a two way valve, 200 cc. of filtered air was slowly injected. Although no manometric check was made on the pressure, no excessive force was exerted.

The patient remained perfectly rational during the injection, but two or three minutes later her body suddenly became rigid and extended in the opisthotonos position. There was an immediate loss of consciousness and control of the sphincters. Her color became cyanotic, the vessels of her neck were dilated and the respirations were labored and irregular. The pulse was thready and the heart sounds were barely audible. No bruit suggestive of air in the chambers of the heart was heard. The blood pressure reading could not be obtained. The eyes were deviated to the right; the pupils were small and contracted and did not react to light. The tendon reflexes were normal.

One hour later the patient regained consciousness. She complained of complete blindness and tingling all over her body. The tendon reflexes were still normal and no sensory changes could be made out. Her vision gradually returned in the course of a few hours.

Six hours after the injection, roentgenograms of the chest and abdomen were taken. The film of the abdomen showed a poor localization of the air, although its presence within the perirenal space was clearly demonstrated (fig. 2). No evidence of the injected air was seen in the film of the chest; there was no pneumothorax and no air in the mediastinum or beneath either cupola of the diaphragm.

For twelve hours after the injection the condition of the patient seemed to improve, but thereafter she became irrational and increasingly restless, despite large doses of opiates. She died twenty-one hours after the perirenal insufflation. The pulse rate had risen to 180 and the temperature reached 102.4 F. just before death.

A necropsy was performed by Dr. Nathan Rudo. Abstracts from the report of the examination follow:

No hemorrhage was found along the path of the injection. There was no gross evidence of injury to any blood vessel, the liver or the right kidney; the kidney was displaced downward and medially by a tremendous enlargement of the liver. No sign of the injected air was found at any point.

The heart, lungs and brain were grossly normal. At the junction of the cecum and ascending colon there was an ulcerated tumor which almost completely encircled the lumen. The liver was riddled with huge masses of tumor tissue, many of which had undergone central cystic degeneration.

Microscopic sections of the brain, lungs and kidneys showed antemortem clots obstructing many of the smaller arteries, veins and capillaries (fig. 3A). In some areas perivascular hemorrhage was also seen (fig. 3B). The primary tumor, as well as the metastatic implants, was typical of adenocarcinoma of the cecum.

Fig. 1.—Bilateral pyelo-ureterogram showing the right kidney displaced downward and medially. An apparent filling defect is seen to resolve in the oblique lateral view (inset). The deformity suggested by the anteroposterior view is produced by horizontal renal torsion, the kidney being rotated on its transverse axis with the upper pole in a dorsal position.

COMMENT

The patient's clinical course assured the diagnosis of air embolism. The cerebral manifestations localized the lesions to the brain and precluded a purely circulatory failure or air emboli of the coronary vessels.

It is interesting to speculate on the route taken by the air in entering the blood stream. The roentgenographic evidence demonstrated that the air originally entered the perirenal space and that it did not penetrate the pleural cavity, the peritoneal

1. Cahill, G. F.: Air Injections to Demonstrate Adrenals by X-Ray. J. Urol. 34: 238 (Sept.) 1935.

cavity or the mediastinum. From the perirenal space it may have found its way into one of the friable veins which are so numerous in the fatty tissue surrounding the kidney; it may have dissected along the vascular pedicle or renal pelvis to gain entrance into a branch emptying into the renal vein close to its origin or to invade the vascular parenchyma through the sinus renalis. The possibility must be considered also that, in

Fig. 2.—Area of the right kidney six hours after perirenal insufflation. Although the air is still poorly localized, its position within the perirenal space is clearly demonstrated by a dark crescentic shadow which outlines the lateral and inferior borders of the displaced right kidney, as indicated by the arrows.

addition to a primary invasion, the air may have entered the venous system by way of the cisterna chyli and thoracic duct.

Regardless of the route taken, it is evident that the communication must have been extremely small or some gross hemorrhage would have been apparent. In this connection the recent experimental studies of Villaret² and his co-workers are illuminating because they indicate that the size of an embolus is of far less importance in causing death than is generally believed.

As Mathé³ has emphasized, air is more likely to enter the circulation in the presence of any injury or disease of the adjacent blood vessels. It only increases the risk of an already dangerous procedure, therefore, to drive the point of the needle into the cortex of the kidney as a step in injecting the perirenal space, as recommended by Gianturco and Drenckhahn,⁴ or to have the patient perform rowing exercises after the injection in order to work the air around the kidney, as advised by Mencher.⁵

If it were possible to introduce air into the body at a pressure lower than that in the veins which lie in the vicinity, the procedure should be harmless enough. Unfortunately the normal venous pressure is little higher than the atmospheric pressure (15 mm. of mercury in the venules, falling to 5 mm. in the larger veins, according to Eyster⁶), and, as the vena cava is reached, the venous pressure becomes negative in respect to the atmospheric pressure, although it is positive as compared to the intrathoracic pressure. Since air occasionally penetrates the mediastinum during injection, this relationship bears directly

on the problem of perirenal insufflation. Gianturco and Drenckhahn⁴ recommended injection at a pressure not exceeding 3 cm. of mercury, yet this is 15 mm. greater than the pressure in the venules and 25 mm. higher than that in the larger veins. In spite of the fact that the lowest pressure at which air can be injected into the perirenal space does not completely eliminate the danger of air embolism, it is nevertheless a matter of considerable importance to make the injection under as low a pressure as possible.

There is no agreement as to the mechanism of death from air embolism. In cases of massive embolism it is generally conceded that mechanical obstruction of the circulation or pulmonary suffocation may be regarded as constituting the essential factor. In smaller embolisms the immediate cause of death is not so easily explained. Carr⁷ recently brought forward the revolutionary idea that the formation of thrombi rather than the gas alone causes the damage. He observed antemortem intravascular clotting and perivascular hemorrhage (as seen in the case reported) in the organs of experimental animals and human beings following the injection of air intravenously. Death resulted from these changes and not from true air emboli.

CONCLUSION

The danger of death from air embolism renders perirenal insufflation a hazardous procedure. If utilized at all, this diagnostic aid should be reserved for that small group of patients for whom the observations made by its use may prove of extraordinary value. In order to reduce the danger to a minimum, care should be exercised to avoid traumatization of the surface of the kidney and the tissues injected, and the injection should be carried out under as low a pressure as possible. Any damage to a vein, even though the vessel is of small dimensions, is a potential site for the entrance of air.

Should an unidentified mass cause a displacement of the kidney a great deal may be learned concerning its location by pyelography and a proper interpretation of the torsion which is present.⁸ As concerns the detection of less pronounced enlargements, such as small tumors of the adrenal gland, perirenal insufflation has in my experience yielded equivocal results.

If, after exhausting the innocuous diagnostic methods at one's disposal, further study of the retroperitoneum is indicated, it seems to me that exploratory operation is more desirable than perirenal insufflation. While perhaps carrying a slightly higher risk, open operation assures an accurate diagnosis and affords

Fig. 3.—Section of the brain following death from air embolism: A, antemortem clot occluding a capillary (high power); B, area of perivascular hemorrhage surrounding a small artery and vein (low power).

the immediate opportunity for the performance of any curative operation which is found to be indicated. The simultaneous exposure of both adrenal glands, according to Young's⁹ technic, adds little to the risk of a unilateral procedure and has much to recommend it when confusion exists as to which gland should be explored.

BLINDNESS DUE TO AIR EMBOLISM: A COMPLICATION OF EXTRAPLEURAL PNEUMOLYSIS

FRANK B. WALSH, M.D., AND H. KRIEGER GOLDBERG, M.D.
BALTIMORE

Our purpose in this report is to draw attention to the occurrence of an air embolus in the eye and to record two cases in which this was observed as a complication of extrapleural pneumolysis.

REPORT OF CASES

CASE 1.—History.—F. C., a Negro woman aged 27, was admitted to the Baltimore City Hospital in August 1936. A diagnosis of pulmonary tuberculosis was made and treatment with pneumothorax was instituted. In February 1937, because of unsatisfactory collapse, this therapy was discontinued. Nov. 11, 1938, a first stage thoracoplasty was performed. The first, second and third ribs on the left side were resected and an extrapleural apicolysis was done. Following this procedure pneumothorax treatment was resumed.

December 15, 120 cc. of air at a pressure of 220 mm. of water was injected. Immediately after this procedure the patient complained of excruciating pain in the head and within a few moments exclaimed that she could not see. She became nauseated and vomited. The pupils were constricted. She feared approaching death. She rapidly became disoriented. A sedative (one-fourth grain [0.016 Gm.] of morphine) served partially to control her restlessness. She passed gradually from a state of confusion into coma, interrupted by generalized convulsions, which occurred many times a day for three days. Improvement then ensued and by the fifth day she was well oriented and was able to feed herself. Results of general and neurologic examinations were negative except for those of the ocular examination.

Examination of the Eyes.—The ocular fundi were not examined during the early hours of this attack. At the onset the pupils were constricted and failed to react to light. Ophthalmoscopic examination was made twelve hours after onset of the illness and was reported as negative. A cycloplegic had been used and this eliminated further observations on the motility of the pupil. There were no apparent extra-ocular palsies at any time. Eighteen hours after the onset there was a low grade retinal edema, most pronounced in the maculae. This edema persisted for one day. The nerve head and vessels appeared normal. The patient did not perceive light. On the fourth day vision was limited to hand motion with either eye, and on the fifth day, after further improvement, the visual acuity was 20/200. Field defects, if present, were not discovered. At examination on the fifth day the only remaining defect was impairment of vision. Visual acuity steadily improved thereafter, so that within nine days after the accident the vision was 20/15 in both eyes and she could read small print with ease.

CASE 2.—History.—R. D., a Negro youth aged 20, was seen at the Johns Hopkins Hospital in July 1937, at which time a diagnosis of pulmonary tuberculosis was made. He was admitted to the state sanatorium, where he remained for one year. His condition became progressively worse and in April 1939 he was admitted to the Johns Hopkins Hospital for surgical intervention. April 15 a left-sided extrapleural pneumolysis was done. The following day 500 cc. of air was injected. Two hours later the patient suddenly complained that he could not see, and a complete motor paralysis of all four extremities was found. He rapidly became disoriented and feared approaching death. At the onset the respirations became shallow; the pulse rate increased and he was nauseated and vomited. He was placed in an oxygen tent and given morphine for sedation. Later in the evening occasional spasmodic contractions of the left leg were observed. The paralysis on the right disappeared by the following morning, but for four days clonic contractions persisted in the left leg. On the sixth day the patient was able to move and use the left arm, but the left leg remained paralyzed. He became com-

pletely oriented and gradual improvement continued, but on the twelfth postoperative day a bronchocutaneous fistula and signs of sepsis developed. Following this the course was steadily downhill. He died three weeks later. Autopsy was not obtained.

Examination of the Eyes.—Examination was recorded two hours after the onset of the accident. The pupils were dilated and fixed to light. The retinas were extremely pale, but the state of the vessels was not described. Four hours later the pallor of the retinas had disappeared and the vessels were normal. The pupils remained dilated. The patient appeared to be completely blind. The extra-ocular movements were observed to be normal during brief periods when the patient cooperated. This situation persisted for three days, and on the fourth day he was able to perceive light with either eye and there was a return of pupillary constriction on exposure to light. On the fifth day visual acuity was equal to hand motion. Gradual improvement continued thereafter, and within two weeks vision had become 20/20 and Jaeger I in both eyes. The eyes remained normal.

COMMENT

From a review of the literature and on the basis of the two cases herein reported we have attempted to summarize the important facts regarding air embolism as it affects the eyes.

Mechanism.—The mechanism¹ of air embolism is not entirely clear. It would seem that prerequisites for the occurrence of air embolism are (1) open or wounded veins, (2) available air and (3) either pressure on the available air so that it is forced into the veins or a negative pressure within the veins so that the air is pulled into them. If veins are cut across, they cannot readily collapse when they are suspended in fibrous tissue. Pulsating arteries adjacent to these veins may contribute a negative pressure within the veins, so that a wound within the vessel becomes a veritable suction valve. In human beings² the amount of air necessary to cause symptoms is not known. Accidental introduction of air into the veins rarely results in untoward symptoms.

Experimental injections of air into the carotid artery of dogs have been reported by Wever³ as resulting in the immediate pallor of the retinas, engorgement of the veins and generalized convulsions; within five minutes after the injection of air the retinas may again be normal. We have injected air into the carotid artery of an anesthetized dog. Immediately after this injection air appeared in the retinal arteries. With the ophthalmoscope the picture was striking. Glistening rods were seen irregularly placed in the arteries and were most clearly visible at the point of arterial branching. This characteristic picture was transitory and had disappeared within less than one minute. There was some engorgement of the veins and questionable narrowing of the arteries. There was definite pallor of the retinas.

Symptomatology.—The occurrence of symptoms usually follows immediately after the injection of air, but in some instances there may be a lapse of several hours between the injection of air and the onset of symptoms. Case 1 exemplifies immediate occurrence of symptoms, whereas case 2 exemplifies delayed occurrence. Probably the delay in the onset of symptoms in case 2 was due to delay in entrance of air into the vessels.

The symptoms may be described as follows: The patient complains immediately of severe pains in the head, dizziness, nausea and vomiting. In some instances there may be blindness. Fear of impending death is a prominent symptom. The pulse becomes rapid and the breathing shallow and labored. There may be general or localized convulsions. Extensive paralysis may develop. Death may ensue within a few minutes. If, however, death does not occur within the first half hour the prognosis is relatively good. Permanent defects of vision as a result of an air embolus have not been recorded. Hamilton and Rothstein⁴ described cases similar to those here reported. Pronounced improvement of paralysis may be con-

From the Wilmer Ophthalmological Institute of the Johns Hopkins Hospital and University, and the Baltimore City Hospitals.

firmly expected even in severe cases.⁵ In case 1 herein reported recovery was complete; in case 2 there was pronounced recovery but some degree of paralysis remained.

When the eyes are involved, blindness is an early symptom. Because of their transitory nature definite ocular signs, as observed in animals, are rarely seen in human beings. Retinal edema, such as was observed in case 1, may be of such mild degree that it may easily be overlooked. In severe cases blindness may persist for several days, as in our two cases. The pupils may be either dilated or constricted. Paralysis of the extraocular muscles were not seen in our cases but have been reported; conjugate deviation of the eyes has been recorded.⁶ Field defects not apparent in our cases have been reported by others. Barkan⁷ has recorded homonymous quadrantic defects and homonymous hemianopia which disappeared within two weeks.

CONCLUSIONS

Two cases of air embolism as a complication of extrapleural pneumolysis were observed. Both patients were blind for a period of three days. Improvement of vision was gradual and within two weeks it had become completely normal.

The appearance of air in the retinal vessels is a pathognomonic sign of air embolism, but this sign is so transitory that it is rarely seen. Blindness is the most important ocular sign. The prognosis for return of vision is good for patients who survive.

Special Article

THE PHARMACOPEIA AND THE PHYSICIAN

THE TREATMENT OF DEHYDRATION, ACIDOSIS AND ALKALOSIS

DANIEL C. DARROW, M.D.

NEW HAVEN, CONN.

This is one of the second series of articles written by eminent authorities for the purpose of extending information concerning the official medicines. The twenty-four articles in this series have been planned and developed through the cooperation of the U. S. Pharmacopoeial Committee of Revision and THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION.—Ed.

Under various circumstances a syndrome called dehydration develops. The patient shows diminished turgor of the skin, sunken eyes, poor circulation, oliguria and concentration of the blood with respect to red cells and serum proteins. While an inadequate intake of water will produce some of these symptoms, the fully developed picture occurs almost exclusively when, as a result of vomiting, diarrhea, sweating or abnormal diuresis, the body has lost extracellular electrolyte (salts) as well as water. Furthermore, this fully developed picture of dehydration can be produced when extracellular electrolyte is no longer available to the body as a whole because it has been fixed in the inflammatory exudate of a burn. In dehydration the evidences of loss of fluid volume are confined chiefly to

extracellular fluids. The central feature is the deficiency of extracellular electrolyte, since dehydration can develop either with or without loss of water from the body as a whole.

In order to explain the treatment of dehydration, the factors controlling the distribution of body water will be briefly described.¹ About seven tenths of the body weight is represented by water, which is distributed in two physiologic compartments. The water outside the cells constitutes about 25 per cent of the body weight in adults and about 35 per cent in newborn babies; the water inside the cells makes up about 50 per cent of the body weight. Although cellular membranes separate these two compartments, the water is free to move between the two in response to osmotic forces. Since the effective osmotic pressure of these two compartments is largely due to potassium in the case of intracellular water and to sodium in the case of extracellular water, the distribution of these two univalent bases is the chief factor controlling the distribution of body water.

The characteristic feature of extracellular fluids is that they contain large amounts of bicarbonate, chloride and sodium and but small amounts of magnesium, phosphate and potassium. Blood plasma, lymph, interstitial fluid and cerebrospinal fluid are the chief examples of extracellular fluid. Since these fluids are in free communication with blood plasma through the capillary membranes, they resemble one another closely except in their protein concentration. The intestinal secretions, gastric juice and bile may be considered modified extracellular fluids which are normally reabsorbed. Furthermore, sweat resembles extracellular fluid, and urine is a highly modified capillary ultrafiltrate of plasma which is excreted in order to preserve the composition of all body fluids. Not only are the extracellular fluids the cellular environment which must be kept fairly constant by renal activity but they are the vehicle for carrying nutrition to the cells, the means of taking waste products away from the cells, the source of digestive fluids and the source of urine. It is not surprising, therefore, that disturbances of these fluids affect all parts of the body.

The fluid within the cells contains almost exclusively potassium and magnesium as basic ions, and proteins and organic phosphate as acid ions. Although the amount and concentration of potassium, magnesium, phosphate and protein within the cells are known to vary, actual analyses of tissues of animals have demonstrated that the relation of the amounts of these substances to one another is surprisingly constant. This constant relationship between the principal constituents of cells can be shown to persist in starvation, in fever, in thirst and after loss of extracellular electrolyte. Although variations in the water content of cells can frequently be demonstrated, these changes can usually be accounted for by changes in the concentration of sodium in extracellular fluid. Thus, although cellular constituents (phosphate and potassium) undoubtedly cross cellular membranes in response to nutritional or functional needs of the cells, the osmotic equilibrium in response to changes in concentration of sodium in extracellular fluid is attained principally by shifts of water.

The term dehydration is retained because it is the one in general use and is no more objectionable than the other terms proposed, namely exsiccosis, anhydremia and hypohydration. Deficiency of extracellular water and electrolyte fits present concepts well but for obvious reasons will never be accepted as a name for a common condition. Acidosis and alkalosis are discussed only as far as they are manifestations of dehydration.

(Gamble, J. L.: *Extracellular Fluid*, *Bull. Johns Hopkins Hosp.* 61: 151, 174 (Sept.) 1937. Peters, J. P.: *Body Water*, Baltimore, C. C. Thomas, Publishers, 1935. Darrow and Yannet.)

and the composition² of cytoplasm is not subject to great changes brought about by osmotic forces outside the cells.

In addition to protecting the composition of the cells, the type of osmotic equilibrium existing between intracellular and extracellular fluids explains why the volume of extracellular fluid cannot be maintained without normal amounts of sodium and chloride even if the total body water remains unchanged. To illustrate the point, one may conceive that a loss of sodium chloride from the body occurred without change in body water. This would reduce the osmotic pressure of extracellular fluids. However, since the intracellular fluids lose no electrolyte in response to this decrease in extracellular electrolyte, the osmotic pressure within the cells must attract water from the extracellular fluids. The shift of water will bring about osmotic equilibrium, but intracellular water will be increased while extracellular water will be decreased. This reaction is readily demonstrated in animals³ and is accompanied by all the symptoms and signs of clinical dehydration. Observations on patients lead to the same conclusion. For instance, in certain patients with low concentration of sodium in serum all the symptoms and signs of dehydration develop. After treatment with physiologic solution of sodium chloride all these signs and symptoms disappear and serum concentrations return to normal. Since no gain in weight occurs, no change in body water has taken place during the obvious recovery of extracellular volume. Consequently one may conclude that the retention of sodium chloride made it possible to increase the volume of extracellular fluids by attracting water from the cells. Similar states of decreased volume of extracellular fluids and increased volume of intracellular fluids in both man⁴ and animals⁵ can be shown to persist for days if no sodium chloride is given. The observations demonstrate the importance of the content of extracellular electrolyte for the distribution of body water and the futility of treatment of dehydration by water and dextrose solutions alone.

Changes in the electrolyte pattern (or acid-base equilibrium) of the serum are frequent accompaniments of loss of extracellular water and electrolyte. If the loss of sodium is greater than the loss of chloride, relatively less than the normal amount of sodium is available to form bicarbonate. This condition results in acidosis. In alkalosis more than the normal concentration of bicarbonate is found in serum as a result of the relatively greater loss of chloride than sodium. Through the study of the composition of gastric juice, pancreatic juice, bile, diarrheal stools, urine and sweat, the various types of loss of extracellular electrolyte can be characterized as to their effect on acid-base equilibrium. In this sense most cases of acidosis and alkalosis may be regarded as special manifestations of deficit of extracellular electrolyte.

During deficiency of extracellular water and electrolyte a number of disturbances in renal function develop.⁶ Thus when water is drunk during dehydration it is excreted more slowly than is normal despite a low concentration of sodium and chloride. When small deficits of sodium exist, the kidneys may eventually restore serum concentrations by excreting extracellular water. However, if large deficits of sodium persist for days, the concentrations of the serum remain low because the kidneys do not diminish the volume of extracellular fluid in order to preserve concentrations. Retentions of urea are explained by the reduction in glomerular filtrate. Moreover, when large deficiencies of sodium and chloride are present the kidneys fail to adjust the acid-base equilibrium of the blood, i.e. they fail to excrete the relative excess of chloride in acidosis and the relative excess of sodium in alkalosis. The explanation of these anomalies is not clear; in part they are brought about by the circulatory failure of dehydration, but in part they are probably dependent on the fact that the function of renal tubules is best carried out when serum concentrations are normal. These points are important, for they disclose that sodium chloride as well as water is necessary for restoration of renal function in dehydration.

Considerable quantities of potassium, phosphate and nitrogen are excreted at the time of the loss of sodium and chloride during the development of dehydration. While the interpretation of the losses of cellular constituents cannot be given with certainty, the losses tend to occur in such proportions as to indicate that cellular structures are breaking down as a whole. Furthermore, tissue analyses indicate that the cellular constituents have surprisingly constant relationships to one another. I believe that the losses of cellular constituents are the result of destruction or of utilization of cellular structures. Hence the decreases in amount of cellular water in the body are not the result of a specific deficiency of potassium, which, if replaced, would restore cellular water. From a therapeutic point of view the restoration of cellular water and electrolyte is not a simple process of providing water, magnesium, phosphate and potassium but a problem in nutrition which can be treated only with food.

It must be kept in mind that all types of marked dehydration are accompanied by the essential features of shock. By shock one refers particularly to the inability of the body to maintain the blood circulation and blood pressure, not primarily because of cardiac failure but rather because of decreases in the volume of circulating fluids and dysfunction of the capillaries.⁷ Sometimes the disturbance is the result of loss of plasma proteins, which may be caused by hemorrhage or by localization of plasma at the site of a traumatic injury or at the site of a burn. However, loss of extracellular electrolyte alone can produce decreased plasma volume. Although plasma volume is maintained for a time at the expense of interstitial fluids, continued loss of extracellular electrolyte leads to diminished plasma volume. Part of the picture of vascular collapse is thought to be dependent on arteriolar constriction,⁸ which, although it preserves the circulation to the brain, aggravates the deficiency in circulation elsewhere. If the plasma volume, blood pressure and circulation remain insuffi-

cient for a few hours, secondary changes take place leading to dilatation of the capillaries and leakage of serum proteins into tissue spaces. These features of shock may be prevented by blood (or plasma) transfusions and are sometimes corrected by the same means. However, if severe shock is allowed to persist several hours, no effective therapy is available.

From the foregoing outline of the nature of the disturbances in dehydration, the general aims of treatment of all types are as follows: (1) restoration of sodium chloride along with sufficient water to enable the kidneys to adjust extracellular volumes and concentrations; (2) adjustment of acid-base equilibrium in certain cases of acidosis; (3) treatment of shock. Hypodermoclyses and intravenous infusions of physiologic solution of sodium chloride (or its modifications) are the most reliable means of replacing extracellular water and electrolyte. Intravenous infusions of sodium bicarbonate or sodium lactate are the means of treating acidosis when the saline solutions are inadequate. Although infusions of dextrose temporarily ameliorate various types of shock, the chief reliance must be placed on blood or plasma transfusions.

Although a great deal of sodium chloride can and should be given by mouth to many patients, the various forms of parenteral therapy must be the chief measures used in cases of severe dehydration. This procedure is made necessary not only by the need for quick effects but also by the amounts of the various solutions required. Furthermore, dehydration per se leads to nausea and vomiting, and many of the patients have nausea and vomiting as a cause of the illness. If nausea and vomiting are present, nothing should be given by mouth, since water or food that is vomited not only does no good but does harm by increasing the loss of electrolyte. The same untoward result may be brought about by food, and less often by water, when these aggravate a watery diarrhea. It cannot be emphasized too often that nothing should be done to increase the loss of electrolyte.

The treatment of dehydration is usually carried out first by a hypodermoclysis of physiologic solution of sodium chloride (from 10 to 60 cc. per kilogram of body weight) and an infusion (from 5 to 30 cc. per kilogram) or 5 or 10 per cent dextrose while the blood is being matched for a transfusion. If symptoms of shock are present, a blood transfusion of from 10 to 30 cc. per kilogram of body weight is given as soon as possible. The higher figure is used only in the most severe cases. Patients suffering from massive hemorrhage with dehydration are probably the only adult patients who require maximal amounts of blood, but many babies with severe dehydration require large transfusions. Since it is not possible always to predict which patients with severe dehydration will recover from circulatory collapse when extracellular water and electrolyte have been restored, many patients should be given transfusions who might otherwise recover with saline and dextrose solutions alone. Since hemoconcentration^{8a} may be brought about by shock alone, a high red count is not a contraindication to transfusion. Recent work has shown that the increased viscosity of blood produced by a high concentration of red cells does not greatly increase the burden on the heart since the effective viscosity in arterioles approaches that of plasma, owing to axial flow. Although anemia may

be an additional reason for giving a dehydrated patient a transfusion, shock is the chief indication. When the red cells by hematocrit are very high, plasma transfusion may be substituted for blood.

Many physicians prefer to use a continuous venoclysis⁹ through which physiologic solution of sodium chloride, dextrose solutions and blood are given at a rate of from 1 to 3 cc. a minute. This procedure may be continued for from one to three or more days. The method has certain advantages of convenience to the physician and also is less painful than large hypodermoclyses. Its effectiveness is brought about not primarily by the fact that the solutions are delivered directly into the vein but by the fact that suitable amounts of salt, water and dextrose are supplied to the body and the fact that blood transfusions are carried out in shock. Certain limitations to the method must be realized. In babies, at least, it is difficult to carry out the procedure without tying a cannula or catheter in a vein, and it is difficult to keep the solutions flowing at a rate of less than 1,500 cc. in twenty-four hours. While injecting at a rate of 1,500 cc. in twenty-four hours may not be harmful to babies when continued for about twelve hours, it is probably too fast for longer periods. At a similar rate an adult would be receiving from 10 to 20 liters of fluid intravenously in twenty-four hours. Karelitz¹⁰ injects about 750 cc. in twenty-four hours by tying a cannula in the vein of infants. He recommends using 5 per cent dextrose in physiologic solution of sodium chloride, since it supplies sodium chloride and does not lead to glycosuria, as does 10 per cent dextrose. Blalock has shown that, while intravenous administration of sodium chloride and dextrose temporarily improve the symptoms in shock, relapses are apt to occur and to be severe, owing to aggravation of the loss of plasma proteins. This fact may explain the frequency of edema following venoclysis. When prolonged intravenous injections of dextrose are suddenly stopped, hypoglycemia develops. In using venoclysis on adults, from 2 to 3 liters in twenty-four hours is apparently a suitable rate, though 5 liters has been given with good results. In babies from 750 to 1,000 cc. is probably a safe amount. When the deficits of salt are greater than is contained in these amounts of physiologic solution of sodium chloride, hypodermoclysis can be used to supplement the venoclysis. In most cases from 5 to 7 per cent dextrose should be added to physiologic solution of sodium chloride for babies, but 10 per cent dextrose added to saline solution may be used in adults. When salt is not necessary, dextrose solutions alone may be used.

No rule can be given as to how much sodium chloride must be given to a dehydrated patient. Recovery from clinical evidences of dehydration and a diuresis containing chloride may be used as guides. However, in adrenocortical insufficiency and in certain cases of hyposthenuric nephritis, excretion of chloride occurs even when body chloride is deficient. From data on animals and patients, I estimate that about one third of the extracellular electrolyte is lost in marked dehydration. For restoration of extracellular electrolyte in such cases, an amount of salt contained in physiologic solution of sodium chloride equal to from one fifteenth to one twelfth of the body weight (about 70 cc. per kilogram of body weight) is required. Smaller amounts

8a. By hemoconcentration reference is made to loss of plasma water, which leads to a rise in the proportion of red cells by hematocrit and to increase in the concentration of serum proteins if these are not simultaneously lost for the circulation.

are needed in mild cases. When symptoms leading to loss of electrolyte continue, administration of physiologic solution of sodium chloride must be repeated.

In acidosis, hyperpnea usually indicates when sodium bicarbonate or sodium lactate is advisable. However, it is safest to calculate the dose necessary to restore the serum bicarbonate according to the method of Hartmann and Senn.¹¹

$$\text{mM} = \frac{(60 - \text{CO}_2) 0.7W}{2.24}$$

In the equation, mM is millimols of sodium bicarbonate or sodium lactate. One millimol of sodium bicarbonate is 0.084 Gm. One millimol of sodium lactate is contained in 1 cc. of molar sodium lactate; CO_2 is the serum carbon dioxide content in volumes per cent, and W is body weight in kilograms.

In marked acidosis when serum carbon dioxide is not known, 5 millimols of sodium bicarbonate (0.4 Gm.) per kilogram of body weight is a safe dose. Hartmann recommends the injection of one half the calculated dose of sodium lactate intravenously and one half subcutaneously as one-sixth molar sodium lactate.

Molar sodium lactate is obtainable in sterilized ampules, which most physicians will find more convenient than sodium bicarbonate. Sodium bicarbonate is not obtainable as a sterile solution. Furthermore, it cannot be boiled or autoclaved in an unsealed vessel without forming the highly toxic sodium carbonate. Sodium bicarbonate may be weighed and added with aseptic precautions to sterile water or dextrose solution and injected intravenously in a 2 to 5 per cent solution. Both sodium bicarbonate and sodium lactate may be given by mouth, but in dehydration they are apt to be vomited.

SOLUTIONS USED IN DEHYDRATION

The following remarks on the solutions used in treating dehydration are given to indicate their limitations as well as their usefulness.

Physiologic Solution of Sodium Chloride (0.9 per cent sodium chloride).—Because of the convenience in preparation, physiologic solution of sodium chloride will probably continue to be the most frequently used solution for replacing deficits of extracellular electrolyte. The solution contains relatively more chloride than extracellular fluid, but with normal renal function the relative excess of chloride is excreted so as to free sodium, which may then combine with carbon dioxide to form bicarbonate. In renal disease or when circulatory collapse induces defective renal function, the injection of physiologic solution of sodium chloride may produce or aggravate acidosis. This effect is brought about chiefly by diluting the bicarbonate already in the body at a time when the kidneys are not excreting the excess of chloride. In acidosis this effect may be serious, even when renal function is fairly good, if loss of sodium in excess of chloride continues to occur, as in diarrhea. In most cases physiologic solution of sodium chloride is satisfactory for replacing extracellular electrolyte. It may be injected intravenously or subcutaneously.

Interstitial Salt Solution (sodium chloride 6.5 Gm., sodium bicarbonate 2.5 Gm. and potassium chloride 0.18 Gm. per liter).—Because of the presence of sodium bicarbonate, this solution must be autoclaved in sealed ampules. Fifty cc. ampules containing enough of the salts to make an interstitial salt solution when added

to 500 cc. of sterile water are on the market.¹² This mixture closely resembles interstitial fluid in its electrolyte content. It has none of the disadvantages of physiologic solution of sodium chloride. In fact it may be used in practically all cases of acidosis without additional sodium bicarbonate. The solution may be given subcutaneously or intravenously. The disadvantages are a moderate increase in cost.

Lactate-Ringer's Solution (sodium chloride 6 Gm., sodium lactate 2.7 mg., potassium chloride 0.4 Gm. and calcium chloride 0.2 Gm. per liter).—This solution is prepared in concentrated form in ampules the contents of which are to be diluted twenty-five times with distilled water.¹³ After absorption the lactate is metabolized so that the sodium lactate is converted to sodium bicarbonate. Its uses and advantages are the same as interstitial salt solution.

Dextrose Solutions.¹⁴—Solutions may be prepared by autoclaving dextrose (*d*-glucose) added to distilled water. However, owing to occasional febrile reactions with these preparations most physicians will prefer to add a 50 per cent solution sterilized in ampules to freshly distilled water. Although concentrations up to 50 per cent have been given intravenously, 5 or 10 per cent is the strength usually employed. High concentrations are irritating if they get outside the vein and may produce thrombosis. Dextrose solutions are given for their temporary value in shock, for their antiketogenic effect in ketosis, for their food value when food cannot be taken in adequate amounts by mouth, and finally as a source of water without salt. Dextrose solutions do not supply salt, so they cannot replace extracellular electrolyte, which is the most important loss in dehydration. However, by providing food and aiding the circulation, dextrose solutions help the kidneys to adjust extracellular volume and concentration when sufficient sodium chloride is available. When a patient who has no deficit of extracellular electrolyte must be given all fluids parenterally, intravenous dextrose provides a solution without salt which may be needed to take care of the imperceptible water loss. However, even abnormal kidneys excrete salt solution well if serum proteins are not reduced or cardiac failure is not present. Dextrose may be added to saline solutions for intravenous injection. The body can handle about 1 Gm. of dextrose per kilogram of body weight an hour. With continuous injection the amount of dextrose that can be utilized gradually increases. A small amount of glycosuria is harmless, but large amounts over prolonged periods are to be avoided.

I believe that the general practice of giving so-called isotonic solution of dextrose (5.5 per cent) subcutaneously is seldom justified, since it is irritating locally and over a period of several hours immobilizes water and extracellular electrolyte.¹⁵ In a dehydrated patient this may aggravate an already dangerous depletion of extracellular water and electrolyte. The addition of 5 per cent dextrose to physiologic solution of sodium chloride does not get around this difficulty. A mixture of 2.5 per cent dextrose U. S. P. and 0.45 per cent sodium chloride (i. e. equal parts of physiologic solution of sodium chloride and 5 per cent solution of dextrose)

12. Prepared by Sharp & Dohme Company, Philadelphia.

13. Prepared by Eli Lilly & Co., Indianapolis. This firm also prepares molar sodium lactate.

14. Several well known firms prepare satisfactory ampules of 50 per cent dextrose.

will not withdraw and localize appreciable amounts of extracellular water and electrolyte.

Acacia.—Ampules of 30 per cent acacia suitable for intravenous injection are available. This solution should be diluted to 6 per cent in physiologic solution of sodium chloride and injected slowly into the veins in amounts varying from 5 to 10 cc. per kilogram of body weight. The evidence seems clear that occasional deaths have followed intravenous injections of solutions which probably were properly prepared. Mild reactions are not infrequent. The injected acacia is taken up by the hepatic cells and remains in the cells for months or years. The latter feature seems especially dangerous when repeated doses are given, as has been recommended in nephrosis. The evidence, however, is equally clear that patients in shock can often be saved by acacia, but blood or plasma transfusions will serve the same purpose without similar risks. I believe that the use of acacia should be limited largely to patients in shock who cannot be quickly given transfusions with blood or plasma.¹⁶

SPECIFIC DISEASES

The following remarks on specific diseases or disturbances are given together with a recent reference in order to enable the reader to work out a method of treatment in the light of recent concepts.

Diarrhea.¹⁷—The loss of electrolyte in diarrheal stools resembles the loss of pancreatic juice in its effect on the body; i. e. more sodium than chloride is excreted, and acidosis is the rule. Although physiologic solution of sodium chloride is usually satisfactory for replacing the deficit, interstitial salt solution or lactate-Ringer's solution is more appropriate.

Diabetic Coma.¹⁸—During the development of coma, large amounts of sodium chloride as well as salts of keto-acids are excreted. This aspect of diabetic coma requires the administration of large amounts of sodium chloride and frequently sodium bicarbonate as well. I have used interstitial salt solution and have not felt the need of additional sodium bicarbonate. However, certain cases do require sodium bicarbonate (or sodium lactate), especially if physiologic solution of sodium chloride is the means used to replace extracellular electrolyte.

Nondiabetic Ketosis.¹⁹—Although ketosis occurs at all ages, severe acidosis in patients not suffering from diabetes occurs almost exclusively in young children, especially those under 2 years of age. As a result of vomiting, large deficits of extracellular electrolyte must be replaced by interstitial salt solution, lactate-Ringer's or physiologic solution of sodium chloride. Intravenous administration of solution of dextrose is also indicated to overcome ketosis. Insulin is undesirable.

Nephritis.²⁰—In cases of acute nephritis, vomiting an alkaline gastric juice is the chief cause of the mild

degree of acidosis seen. Although the patients are edematous, the serum concentrations of sodium are usually low. Interstitial salt solution (from 300 to 500 cc.) is often indicated, since it promotes diuresis. Intravenous administration of solution of dextrose is often made to increase the volume of urine, but its use has been disappointing in my experience.

In cases of chronic nephritis vomiting may in part be a cause of dehydration and acidosis. In addition, the kidneys, which form urine of fixed specific gravity, usually excrete sodium and chloride, even when the serum concentrations are low. Furthermore, excretion of an excess of acids leads to loss of sodium. In such cases deficiency of extracellular electrolyte often develops, especially if the patient is given a low salt diet. Often urinary excretion is improved by the addition of a mixture of sodium chloride 6 Gm. to sodium bicarbonate 2 Gm. to the diet in such amounts as to permit replacement of daily urinary loss. However, since chloride and sodium are not well concentrated in the urine by these patients, abnormally high concentrations of serum may occur.

Vomiting.—In cases of pyloric obstruction the vomited gastric juice is apt to be quite acid and its loss lead to alkalosis. While clinical alkalosis with symptoms of tetany is rare, chemical alkalosis with symptoms of dehydration is quite frequent. Although other types of vomiting can give the same result, the vomiting of nephritis, recurrent vomiting of children and that of some infections is probably alkaline, since these diseases are accompanied by acidosis. In alkalosis physiologic solution of sodium chloride is the appropriate treatment, but in acidosis one of the balanced solutions may be more appropriate.

Burns.²¹—The inflammatory exudate of burns is made up of plasma proteins, sodium chloride and water. Since the extracellular electrolyte is fixed at the site of the injury, the rest of the body suffers from deficiency of sodium chloride and sodium bicarbonate. In addition, if a patient with a burn is put in a tub containing water, the denuded surface is no barrier to the diffusion of extracellular electrolyte, and hence continuous tubs can of themselves lead to marked deficiency of extracellular electrolyte. Water in tubs or wet dressings used for treating extensive burns should contain sodium chloride at physiologic strength (9 Gm. per liter) or, better, sodium chloride 6 Gm. and sodium bicarbonate 2.5 Gm. per liter. The loss of plasma proteins makes transfusions essential for extensive burns. Physiologic solution of sodium chloride, interstitial salt solution or lactate-Ringer's solution must be given in maximum amounts in extensive burns.

Traumatic Shock.—Blalock⁷ and others have demonstrated that plasma protein, water and electrolyte escape the capillary walls at the site of traumatic injury. These losses, as those in burns, must be treated with transfusions and saline solution.

Addison's Disease.²²—Adrenocortical insufficiency is accompanied by the excretion of sodium and chloride in

the urine even when serum concentrations are abnormally low. However, in addition, potassium is not excreted except at a low urinary concentration even though serum concentration is high. As deficit of body sodium and chloride develops, the defect of renal function which is characteristic of deficit of extracellular electrolyte becomes superimposed on the disturbance in renal function due specifically to lack of cortical hormone. Without cortical hormone, sodium chloride must be given to patients with Addison's disease not only to replace the continually recurring deficits of sodium chloride but also to enable the volume of urine to be increased so that sufficient potassium can be excreted even at low urinary concentrations. Except during crises, sufficient sodium chloride can be given by mouth. When large amounts (more than 20 Gm.) are necessary, it is better to give sodium bicarbonate (or equivalent amounts of sodium lactate or citrate) along with sodium chloride in the proportions found in serum (i. e. sodium chloride 6 Gm. to sodium bicarbonate 2.2 Gm.). Lowering the intake of potassium lessens the requirement of sodium salts. While sodium salts do not restore all the functions that are carried out by cortical hormone, many patients can be kept alive with salt alone. Until recently salt seemed to be necessary for treatment even in conjunction with cortical extracts. The synthetic product desoxycorticosterone seems particularly effective in restoring renal function and, after any initial deficit has been replaced, large amounts of salt are contraindicated during treatment with this compound.

Heat Prostration and Heat Cramps.²³—Sweating caused by hot weather or work in hot places can produce large deficits of sodium chloride. Usually water is drunk by patients having heat cramps, so that the deficit of sodium and chloride is greater than that of water. Sodium chloride relieves the patient, and salty meals or 0.1 per cent solution of sodium chloride used as drinking water will prevent the disturbance. In certain cases the mechanism regulating body temperature ceases to function and temperatures of from 40 to 45 C. (104 to 113 F.) may develop. Although deficits of salt should be treated in these cases, reduction of the body temperature by ice tubs is imperative, since permanent brain damage can be produced by the fever alone.

SUMMARY

The treatment of dehydration is the replacement of the deficit of extracellular electrolyte and water and maintenance of blood circulation and volume. Administration of solutions containing sodium chloride will correct the disturbance in the electrolyte pattern in alkalosis and in moderate acidosis. A balanced salt solution is advantageous in all types of severe dehydration, when renal function is defective or when continued loss of extracellular electrolyte may be expected. Sodium bicarbonate or sodium lactate can be given for severe acidosis. The maintenance of blood volume and circulation is essentially the treatment of shock, namely blood or plasma transfusion, intravenous infusion of dextrose and, at times, salt solutions.

Council on Pharmacy and Chemistry

REPORTS OF THE COUNCIL

THE COUNCIL HAS AUTHORIZED PUBLICATION OF THE FOLLOWING REPORTS.
PAUL NICHOLAS LEECH, Secretary.

OVARIAN CONCENTRATE GLANULES, ANTI-MENORRHAGIC FACTOR GLANULES AND OVARIAN-ANTERIOR PITUITARY LIQUID NOT ACCEPTABLE FOR N. N. R.

Several products of the Armour Laboratories—Ovarian Concentrate Glanules, Anti-Menorrhagic Factor Glanules and Ovarian-Anterior Pituitary Liquid—have been advertised recently to physicians.

Ovarian Concentrate is marketed by Armour Laboratories for the treatment of acne, headaches, hypertrichosis and other disturbances incident to the sex cycle. According to the firm's circular, this preparation contains a "sterole fraction free from demonstrable estrogenic properties derived from the fat and lipid fractions of whole ovaries by a special process originated in the Armour Laboratories." The firm fails to explain what physiologic activity is possessed by this fraction of the ovary as determined by appropriate experimental investigation. No bio-assays of any sort are included in their description of product. The firm states: "The main beneficial influence of Special Ovarian Concentrate Armour is on the skin, not merely at puberty, but throughout the entire gonadal active period." Other claims for therapeutic application of this material are: "Special Ovarian Concentrate therapy has been reported to be beneficial occasionally in relieving the unpleasant symptoms, particularly headache, associated with dysmenorrhea and periodic acne . . ." and "Some clinicians have obtained promising results with Special Ovarian Concentrate Glanules in hirsutism associated with the adreno-genital syndrome." It is also mentioned that this material will lower blood pressure, which in certain patients, according to the firm, is desirable. The clinical data presented is quite meager, consisting of several testimonials as to its therapeutic value in acne and headaches. This evidence is obviously not based on sound experimentation, nor is it in accord with accepted scientific principles. The actual mechanism by which the claimed therapeutic responses are obtained is a deep mystery to even those who are well acquainted with the physiologic functions of the ovary.

Other than for progestin, animal ovaries have been found to be an unsatisfactory commercial source for ovarian hormone. If there is any evidence that factors can be extracted from ovaries other than progestin, the Armour Laboratories is obligated to publish this information. Conclusions must depend on the available literature, which at the present time does not supply adequate data to support the advertising claims.

A new concept of menorrhagia heretofore undescribed in the scientific literature has been developed recently by the Armour Laboratories. In spite of the lack of confirmatory evidence, the firm proposes that a certain sterol fraction of mammalian liver is effective in checking functional uterine hemorrhage. This extract is prepared in the form of "Anti-Menorrhagic Factor Glanules." It is reported by Wiles and Maurer (The Anti-Menorrhagic Factor of Mammalian Liver Fat, *Science* 89:293 [March 31] 1939) that this lipid preparation of liver, which is stated not to be vitamin K, was effective in diminishing the excessive bleeding in cases of functional menorrhagia. Curtis has also written in his textbook (Textbook of Gynecology, Philadelphia, W. B. Saunders Company, 1938, pp. 111 and 404) that Anti-Menorrhagic Factor-Armour was found satisfactory in the treatment of uterine hemorrhage. No other evidence—physiologic or clinical—is available, however, which supports or confirms these claims. In view of the absence of appropriate protocols and sufficient clinical and laboratory data, it appears that the firm has been either premature or over-enthusiastic in promoting this preparation. Certainly, such evidence as is presented in the advertising would not be generally accepted as a sound basis for therapy.

23. Ferris, E. B., Jr.; Blankenhorn, M. A.; Robinson, H. W., and Cullen, G. E.: Heat Stroke: Clinical and Chemical Observations in Forty-Four Cases, *J. Clin. Investigation* 17:249 (May) 1938. Talbot, J.: Heat Cramps, *Medicine* 14:323 (Sept.) 1935. Yarnet and

A third preparation, Ovarian-Anterior Pituitary Liquid, resembles the others in the absence of scientific evidence, either physiologic or clinical, on which to base any claims for therapeutic effectiveness. It is in the nature of a shotgun mixture, supposedly supplying to patients certain ovarian hormones and at the same time stimulating with pituitary gonadotropic hormone the patient's own ovaries. From the firm's claim that each ampule of Ovarian-Anterior Pituitary Liquid is equivalent to 12 grains of fresh anterior pituitary lobe and 30 grains of fresh whole ovarian tissue, it appears certain that the activity in such an ampule cannot possibly amount to more than a few rat units of each hormone, which for therapeutic purposes is insignificant. Apparently the firm has become aware of its doubtful therapeutic value, since in answer to a request from the Council office for information regarding these products it stated that it has discontinued distributing advertising material for Ovarian-Anterior Pituitary Liquid.

It is generally accepted that the recent advances in the field of reproductive physiology have been truly remarkable. In the past decade or so the abundant experimental work has resulted in a rapid development of our knowledge of sex hormones and their use in therapy. Years ago our lack of knowledge of endocrine physiology in general served as an excuse for the administration of certain ovarian preparations whose action and potency were unknown. Today, however, there are excellent preparations available to the physician at reasonable cost which are pure, very potent and whose effects are quite well known. The Armour Laboratories shows an unwarranted amount of optimism in urging physicians to choose preparations of little or no scientific or rational basis rather than the pure, potent preparations whose physiologic and therapeutic actions have been competently investigated in the laboratory and clinic. In view of the present day status of sex hormones there seems to be no justification for the existence of the three products described unless more scientific evidence of their therapeutic worth is reported.

The Council declared Ovarian Concentrate Granules, Anti-Menorrhagic Factor Granules and Ovarian-Anterior Pituitary Liquid (The Armour Laboratories) unacceptable for inclusion in New and Nonofficial Remedies because of the lack of scientific evidence to justify their use and because of unwarranted therapeutic claims.

CHAPPEL LIVER EXTRACT ORAL, CHAPPEL LIVER EXTRACT SUBCUTANEOUS AND CHAPPEL LIVER EXTRACT CONCENTRATED INTRAMUSCULAR OMITTED FROM N. N. R.

Three dosage forms of Chappel Liver Extract manufactured by Chappel Laboratories, Rockford, Ill., have stood accepted in N. N. R. for a number of years. Representatives of the firm recently made inquiry whether or not the products would maintain an accepted status if they were distributed by a firm which has no product accepted in N. N. R. and which is not considered acceptable by the Council. The representatives were informed that the Council could not countenance the distribution of products by firms which have not been recognized by the Council and, therefore, transfer of these products from the Chappel Laboratories to another firm would be an infraction of the rules.

Under date of October 24 the Council was informed of an announcement to the drug trade that the preparations of Chappel Laboratories would be distributed by a firm not recognized by the Council, although the Chappel Laboratories will continue to manufacture and control the composition of the product. The Council feels in this instance that Chappel Laboratories has withdrawn from its agreement to abide by the rules of the Council; the appointment of a second firm as distributor means that Chappel Laboratories is no longer the responsible distributor for the products. The Council, therefore, under its rules, rescinds acceptance of the products Chappel Liver Extract Oral, Chappel Liver Extract Subcutaneous and Chappel Liver Extract Concentrated Intramuscular and announces their omission from New and Nonofficial Remedies.

Council on Foods

ACCEPTED FOODS

THE FOLLOWING ADDITIONAL FOODS HAVE BEEN ACCEPTED AS CONFORMING TO THE RULES OF THE COUNCIL ON FOODS OF THE AMERICAN MEDICAL ASSOCIATION FOR ADMISSION TO ACCEPTED FOODS.

FRANKLIN C. BING, Secretary.

FATS AND OILS (See Accepted Foods, 1939, p. 30).

Pompeian Olive Oil Corporation, Baltimore.

POMPEIAN BRAND OLIVE OIL.

Analysis (submitted by manufacturer).—Specific gravity at 25 C. 0.911, saponification number 195, iodine number 86.32, solidification point of fatty acids 17.5 C., acid number 1.35, acidity as oleic acid 0.69%, cottonseed oil none, sesame oil none, peanut oil none, teaseed oil (Fitelson test) none.

Calories.—9 per gram; 256 per ounce.

Supreme Olive Oil Corporation, San Fernando, Calif.

BENEDETTO BRAND SPECIAL OLIVE OIL, an olive oil further refined by treatment with steam to remove the more volatile substances.

Analysis (submitted by manufacturer).—Moisture 0.04%, total solids 99.96%, ash none, fat (ether extract) 100.00%, crude fiber none, carbohydrates none, specific gravity at 25 C. 0.913%, free fatty acids (as oleic) 0.20%, unsaponifiable matter 0.41%, saponification value (Koettstorfer) 192.5%, iodine value (Wijs) 85.9%, smoke point 185 C., melting point (fatty acids) 26.2 C., cottonseed oil (Halphen test) negative, sesame oil (Baudouin test) negative, teaseed oil (Fitelson test) negative, refractive index at 40 C. 1.4621.

Calories.—9 per gram; 255.6 per ounce.

FOODS FOR SPECIAL DIETETIC PURPOSES (See Accepted Foods, p. 295).

The Chicago Dietetic Supply House, Inc., Chicago.

CELLU BRAND JUICE-PAR ELBERTA FREESTONE PEACHES (HALVES).

Analysis (submitted by manufacturer).—Moisture 86.4%, total solids 13.6%, ash 0.4%, fat (ether extract) 0.5%, protein (N \times 6.25) 0.5%, crude fiber 0.4%, reducing sugar as invert sugar 4.0%, sucrose 5.2%, carbohydrates other than crude fiber (by difference) 11.8%, undetermined carbohydrates other than crude fiber (by difference) 2.6%.

Calories.—0.54 per gram; 15 per ounce.

PREPARATIONS USED IN THE FEEDING OF INFANTS (See Accepted Foods, 1939, p. 156).

Beech-Nut Packing Company, Canajoharie, N. Y.

BEECH-NUT BRAND STRAINED LIVER AND BEEF SOUP WITH VEGETABLES, BARLEY AND RICE.

Analysis (submitted by manufacturer).—Moisture 84.3%, total solids 15.7%, ash 0.6%, fat (ether extract) 1.3%, protein (N \times 6.25) 4.1%, crude fiber 0.3%, total carbohydrates other than crude fiber (by difference) 9.4%, copper 0.000240%, iron 0.00125%, specific gravity 1.061%.

Calories.—0.66 per gram; 18.7 per ounce.

Harold H. Clapp, Inc., Rochester, N. Y.

CLAPP'S BRAND STRAINED PEARS AND PEACHES.

Analysis (submitted by manufacturer).—Moisture 78.9%, total solids 21.1%, ash 0.2%, fat (ether extract) 0.1%, protein (N \times 6.25) 0.3%, crude fiber 0.8%, carbohydrates other than crude fiber (by difference) 19.7%, calcium (Ca) 0.0074%, phosphorus (P) 0.0011%, iron (Fe) 0.0009%, copper (Cu) 0.0003%.

Calories.—0.81 per gram; 23 per ounce.

Gerber Products Company, Fremont, Mich.

GERBER'S BRAND DRY PRE-COOKED CEREAL FOOD, a flaked dried cooked mixture of wheat, semolina, yellow cornmeal, wheat germ, malt, dried brewers' yeast, dicalcium phosphate ($\text{CaHPO}_4 \cdot 2\text{H}_2\text{O}$), sodium chloride, and iron and ammonium citrates (U. S. P.).

Analysis (submitted by manufacturer).—Moisture 5.6%, total solids 94.4%, ash 4.5%, fat (ether extract) 1.3%, protein (N \times 6.25) 12.4%, crude fiber 1.3%, carbohydrates other than crude fiber (by difference) 74.9%, calcium (Ca) 0.675%, phosphorus (P) 0.7989%, iron (Fe) 0.0300%.

Calories.—3.60 per gram; 102 per ounce.

Vitamins.—Report of biologic assay (1939) submitted by the manufacturer indicates that the product contains approximately 2.8 international units of vitamin B₁ per gram, 80 per ounce, and 1.4 Sherman-Bourquin units of vitamin G (riboflavin) per gram, 40 per ounce.

Libby, McNeill & Libby, Chicago.

LIBBY'S BRAND HOMOGENIZED SPINACH.

Analysis (submitted by manufacturer).—Moisture 94.1%, total solids 5.9%, ash 1.4%, sodium chloride 0.9%, fat (ether extract) 0.3%, protein (N \times 6.25) 1.6%, crude fiber 0.8%, carbohydrate other than crude fiber (by difference) 1.8%, calcium (Ca) 23.0 mg. per 100 Gm., phosphorus (P) 7.1 mg. per 100 Gm., iron (Fe) 3.0 mg. per 100 Gm., copper (Cu) 0.227 mg. per 100 Gm.

Calories.—0.16 per gram; 4.5 per ounce.

Vitamins.—Protocols of biologic assay (1939) show that the product contains 16.3 U. S. P. units of vitamin A per gram, 463 per ounce, vitamin B₁ is practically absent; 0.13 Sherman-Bourquin units vitamin G (riboflavin) per gram, 3.8 per ounce; and, according to a report of chemical titration (1939), 0.35 international unit vitamin C per gram, 10.2 per ounce.

SATURDAY, FEBRUARY 24, 1940

THE PLATFORM OF THE AMERICAN MEDICAL ASSOCIATION

The American Medical Association advocates:

1. The establishment of an agency of the federal government under which shall be coordinated and administered all medical and health functions of the federal government exclusive of those of the Army and Navy.
2. The allotment of such funds as the Congress may make available to any state in actual need, for the prevention of disease, the promotion of health and the care of the sick as proof of such need.
3. The principle that the care of the public health and the provision of medical service to the sick is primarily a local responsibility.
4. The development of a mechanism for meeting the needs of expansion of preventive medical services with local determination of needs and local control of administration.
5. The extension of medical care for the indigent and the medically indigent with local determination of needs and local control of administration.
6. In the extension of medical services to all the people, the utmost utilization of qualified medical and hospital facilities already established.
7. The continued development of the private practice of medicine, subject to such changes as may be necessary to maintain the quality of medical services and to increase their availability.
8. Expansion of public health and medical services consistent with the American system of democracy.

COMPARATIVE VALUE OF SERUM THERAPY AND CHEMOTHERAPY IN PNEUMOCOCCIC PNEUMONIA

Serotherapy of pneumococcic pneumonia is specific and is based on the fact that infection with pneumococci provokes in the invaded organism the production of antibodies. These antibodies unite with the antigenic or the capsular carbohydrate, thus rendering the pneumococci sensitized so that they are lysed, phagocytosed and destroyed. The mortality rate of pneumococcic pneumonia, when treated by the type specific serum, has been reported from various sources to be between 2 and 10 per cent. The significant advance presented by this therapy is not without certain minor disadvantages, which must be kept in mind. They are listed by Bullowa¹ as follows: (1) Serum administered must be specific for the infecting type; (2) some types, such as pneumococcus type III, are resistant

to serum; (3) serum must be given intravenously; (4) there is a possibility of anaphylaxis, thermal reactions and serum sickness; (5) serum therapy is expensive. The development of the rabbit serum represents progress since it makes possible, as pointed out by Finland,² treatment of patients who are specifically sensitive to horse serum, particularly those who have previously received injections of horse serum. This applies particularly to type XIV pneumococcus pneumonia, in which horse serum has been known to give rise to severe and even fatal reactions because of its property of agglutinating human erythrocytes of all blood groups. The antipneumococcus type XIV rabbit serum does not possess this property.

In 1938 Whitby reported striking results obtained in experimental pneumococcic infections of mice with sulfapyridine, a sulfonamide derivative. His observations were soon confirmed by Long and his co-workers,³ who demonstrated in animal experiments that the drug is about as efficient as is sulfanilamide in the treatment of experimental streptococcic, meningococcic and Clostridium welchii infections in mice and somewhat superior to sulfanilamide in the treatment of experimental pneumococcic, Friedländer's bacillus and staphylococcic infections in mice. Both investigators state that the new drug, unlike sulfanilamide, is irregularly absorbed and slowly excreted. The presence of the additional pyridine molecule does not make the drug more toxic than the sulfanilamide. In the animal body sulfapyridine exerts a bacteriostatic effect on the pneumococcus. Growth of the organisms is retarded, while the rate of antibody production is undiminished.

Evans and Gaisford⁴ reported 100 cases of lobar pneumonia treated with sulfapyridine. The mortality rate in their experience was 8 per cent as compared with 27 per cent in a controlled series observed at the same time. Flippin and his associates⁵ reported four deaths in a series of 100 cases and state that the drug brought about within twenty-four to forty-eight hours a critical drop in temperature followed by prompt clinical improvement. Similar favorable results are reported by Barnett and his co-workers.⁶ MacLeod⁷ calls attention to certain toxic effects of the drug, such as frequent nausea and vomiting, morbilliform rashes and cyanosis, and Finland² mentions severe mental and physical depression and marked excitement, impaired renal function and one instance of granulocytopenia. Finland also states that a number of cases have been reported in the literature in which,

after treatment with sulfapyridine alone, relapse of the pneumonia occurred in the same or other portions of the lung. Such relapses have occurred from three to ten or more days after complete subsidence of fever and after what was considered to be an adequate dose of the drug.

In view of the almost equally enthusiastic reports regarding these new therapeutic agents, the practitioner is confronted with the problem of choosing the one or the other or the combination of the two. Studies relative to their comparative effectiveness have thus far been few. Finland and his co-workers report a mortality rate of 13 per cent in 167 cases treated with the specific serum alone. The death rate in ninety-five cases treated with sulfapyridine alone was 15 per cent. A group of eighty patients was chosen for combined treatment with sulfapyridine and serum. This group contained a greater proportion of older patients and the incidence of bacteremia was about twice that in the cases treated with serum alone and three times that in the cases treated with sulfapyridine alone. The mortality in this group was only 22 per cent. In similar cases treated without specific serums or drugs the expected fatality rate is between 75 and 90 per cent; with specific serums alone it is from 50 to 60 per cent.

When serum alone is administered, a defervescence occurs after six to twenty-four hours in the great majority of cases, whereas sulfapyridine must be continued for at least forty-eight to seventy-two hours or even longer after the defervescence. Finland feels that sulfapyridine may be started in all cases as soon as the diagnosis of pneumonia is established, with the exception of cases in which there is polymorphonuclear neutropenia. He further feels that the drug, at least for the time being, should not be given to patients with jaundice or known or suspected liver or kidney disease. He would give specific serums as soon as possible to patients over 40 years of age and to all pregnant or recently parturient women in whom any of the common types of pneumococci are found, and in all cases in which the blood cultures yield specific types of pneumococci. He concludes that both specific serums and sulfapyridine are effective agents and that in cases of severe involvement the use of the combination of the drug and specific serum has shown definite effects in reducing the fatality in the severest group, in which the mortality is the highest. Dowling and Abernethy⁸ present a careful clinical study undertaken to evaluate the relative value of the two agents. In a group of ninety cases serum alone was administered and in a group of 130 sulfapyridine alone. The two groups were about similar in severity and were treated at the same time. The total mortality rate for the serum treated group was 16.7 per cent, while that for the sulfapyridine treated group was 11 per

cent. The mortality rate among the patients to whom the serum was administered during the first four days was 10.8 per cent. The mortality rate among thirty-four patients receiving sulfapyridine during the first four days was less than 3 per cent. Sulfapyridine seemed to be more effective for older patients and for patients with involvement of two or more lobes, while the two agents seemed to be of equal value in bacteremic cases. Empyema developed in six of the ninety-six serum treated cases (6.1 per cent) and in four of the 136 sulfapyridine treated cases (2.9 per cent).

The clinical evidence furnished thus far establishes the efficacy of both serotherapy and the new chemotherapy in lowering the death rate from pneumococcal pneumonia. The relative value of the two methods and the indications for their employment, as well as for the combined use of the two, await further clinical studies.

HORMONE REFRACTORINESS

Persistent endocrine therapy often leads to the development of hormone refractoriness. A continuation of the therapy after this condition develops is of little value and may cause deleterious results. Collip¹ and his co-workers showed that hormone refractoriness may develop in experimental animals even though endocrine products from the same animal species are selected and that acquired hormone refractoriness is serologically transferable. Determination of the origin, nature and method of action of the serum component responsible for this transfer is of basic clinical interest.

The refractoriness serum components have been considered to be inhibiting hormones or hormone-destroying enzymes presumably formed as a result of a compensatory hypertrophy of antagonistic endocrine glands. This theory finds some histologic support² and is apparently confirmed by the indirect serologic evidence recently reported by Sulman,³ of the Rothschild Hospital, Jerusalem.

Sulman tested the antigenic properties of a wide range of gonadotropic substances in laboratory animals. He found that rabbits injected with crude gonadotropic substance develop relatively high-titer complement-deviating antibodies in their blood serum. When purified gonadotropic substance is injected, however, either alone or in combination with a protein carrier (swine serum), complement-deviating antibodies are not demonstrable. He concluded from this negative evidence that hormones per se are nonantigenic and do not acquire antigenicity when combined with alien proteins. In his opinion the apparent antigenic properties of crude gonadotropic substance must be attributed to accompanying impurities. Antihormones, therefore, "must be looked upon as protective ferments, but certainly not as antibodies."

A quite different conclusion is currently drawn from indirect physiologic evidence by Gordon, Kleinberg and Charipper,⁴ of the Department of Biology, New York University. It is generally believed by immunologic theorists⁵ that the reticulo-endothelial system is the essential tissue responsible for the synthesis or internal secretion of specific antibodies. The New York investigators therefore tested the effects of reticulo-endothelial extirpation and blockade on the rate of development of hormone refractoriness. They found that a daily subcutaneous injection of pregnant mare serum gonadotropin, for example, caused a rapid initial increase in ovarian weight in normal female rats, maximum weight being reached on the seventeenth day. Endocrine refractoriness became apparent after that date. In spite of continued daily injections of the hormone the ovarian weight rapidly decreased and was reduced to that of untreated controls by the end of two months. In parallel tests with splenectomized female rats the initial rate of ovarian increase was twice as fast and the development of refractoriness delayed till after the twenty-fifth day.

Even more striking differences were obtained by combining splenectomy with reticulo-endothelial blockade, the latter being effected by intraperitoneal injections of trypan blue. Hormone refractoriness, with resulting regression in ovarian weight, was not observed after such complete reticulo-endothelial exclusion even though the daily hormone injections were continued for fifty-five days. Titration of antihormones by serum transfer showed a quantitative parallelism between delayed refractoriness and antihormonal serum titer.

Their conclusion that integrity of the reticulo-endothelial system is essential for the development of hormone refractoriness was confirmed by a study of other hormones. The effects of splenectomy on the development of testicular hypertrophy in male rats following daily injections of gonadotropic substance was in accordance with the same law. The effects of splenectomy plus dye blockade on the metabolic rates of guinea pigs following daily injections of thyrotropic hormone were also confirmatory. Hormone refractoriness developed by the twentieth day in guinea pigs with intact reticulo-endothelial systems but was delayed for at least fifty days in splenectomized dye blockade controls.

Gordon and his colleagues argue that, since participation of the reticulo-endothelial system is essential for the development of hormone refractoriness, it is a logical presumption that antihormones are the result of immunologic adaptations. Antihormones therefore must be considered as true antibodies in spite of their alleged failure to give routine complement deviating test tube reactions. A modification of the routine in vitro technic might conceivably give positive results.

Current Comment

THE NATIONAL CONFERENCE ON MEDICAL NOMENCLATURE

Elsewhere in this issue (page 669) appears the program of the National Conference on Medical Nomenclature, which will be held in Chicago on March 1. The purpose of this conference is to discuss certain problems of medical terminology and classification and probably arrange for their continued consideration by the formation of permanent nomenclature committees. The national societies in specialized fields of medicine have been invited to send delegates to the conference.

PERIPHERAL VASCULAR DISEASE

The February issue of the *Archives of Surgery* is devoted to a symposium on peripheral vascular disease containing contributions from leading authorities in this field. Among the subjects discussed are the treatment of occlusive arterial disease, amputation, differential diagnosis and peripheral vascular spasm from tobacco. Special articles are devoted to surgical intervention on the sympathetic nervous system, heparin in surgical treatment of the blood vessels, the effect of estrogens on vascular spasm and a review of nearly 1,000 cases of diabetic gangrene and other aspects of the problem. The symposium is a mine of information on the latest advances in the knowledge and treatment of peripheral vascular disorders.

EFFECT OF PECTIN ON BACTERIAL GROWTH

Since recognition of the therapeutic value of raw apple in certain diarrheas, a number of investigations have been made on the alleged germicidal action of pectin on intestinal organisms. Recently Prickett and Miller¹ have observed the effect of pectin and nickel pectin on bacterial growth. Their procedure involved the addition of various samples of pectin to nutrient broth and the subsequent incubation in these mediums of typical cultures of *Escherichia coli* isolated from feces. Plate counts were made at various intervals. Control of the pH was carefully observed. Thirteen different commercial pectins were studied. From the results obtained it was concluded that there is no reason to believe that pectin per se is bactericidal and that whatever unfavorable effect on bacterial growth is noted in pectin broth is the result of acidity. A further investigation was made in which nickel chloride in known amounts was added to three different nickel free samples of pectin. The results from the use of these preparations indicated that the bactericidal effect of nickel varies directly with its concentration. The pH of the medium, the buffer effect of pectin and the presence or absence of fermentable material modify but do not essentially change this effect. Clearly, however, the results of these in vitro observations cannot yet be interpreted as explaining the mechanism of action of pectins on the flora of the human gastrointestinal tract.

ORGANIZATION SECTION

NATIONAL PHYSICIANS' COMMITTEE

BOARD OF DIRECTORS MEETS FOR CONSIDERATION OF NEW PROPOSED LEGISLATION

The following report pertaining to the activities of the National Physicians' Committee has been submitted and is published for the information of the readers of THE JOURNAL:

On February 12, at a regular meeting of the Board of Trustees of the National Physicians' Committee for the Extension of Medical Service, action was taken to increase the number of voting trustees from twelve to fifteen members. Because of continuing ill health, Dr. John A. Hartwell tendered his resignation. The resignation was accepted and Dr. Charles Gordon Heyd, of New York, was unanimously elected to fill the vacancy. Drs. Harvey B. Stone, Baltimore, James A. Paullin, Atlanta, Ga., Edward J. McCormick, Toledo, Ohio, and Charles Dukes, Oakland, Calif., were elected to membership on the Board of Trustees.

The organization setup of the National Physicians' Committee for the Extension of Medical Service consists of a Central Committee, now numbering more than 425 physicians, on which every state has representation and which is being constantly increased; a Board of Trustees, of which Dr. Edward H. Cary, Dallas, Texas, is chairman, Dr. Austin A. Hayden, Chicago, secretary, and Dr. N. S. Davis III, treasurer, and a Management Committee of five of the trustees. Drs. Cary, Hayden and Davis are members of the Management Committee. At the Chicago meeting Dr. W. F. Braasch, of Rochester, Minn., and Dr. Edward H. Skinner, of Kansas City, were elected to membership.

Chairman Cary reported in detail on the prospect of federal legislation during the present session of Congress. According to this report there was the likelihood of the President's hospital bill being enacted into law. He considered this of lesser importance than the prospect of a continuation of adverse propaganda that was confusing the people and tending to destroy the confidence of the public in the effectiveness of American

medicine and in the practicing physician. He pointed out that the National Physicians' Committee had assumed a tremendously important responsibility and undertaken an exceedingly difficult task. He indicated that the initial response from the profession had been gratifying beyond all expectations.

Dr. Hayden, as secretary, presented a report that was unanimously approved. This report indicated that the response had been actually nationwide, with physicians from every state sending contributions and participating by way of Central Committee membership. In order of the amount of contributions, Illinois was first and Pennsylvania second, closely followed by New York, Minnesota, California, Texas and Ohio, with Connecticut and Washington making the best relative showings on a basis of population. It was reported that many county medical societies and clinics had contributed to the support of the Committee.

Dr. N. S. Davis III, as treasurer, submitted a financial statement which indicated that, with a continuation of the support of physicians, a sound financial structure would result that would insure effective action.

Executive Administrator John M. Pratt reported that the board of directors of the National Retail Druggists Association had voted approval and for active cooperation and that the Drug and Pharmaceutical Manufacturers groups and the owners of medical buildings throughout the United States were most sympathetic. In addition, hospital executives and members of the dental profession are interested.

In adjourning, Chairman Cary stated that there was no doubt as to the need for the organization, the importance of the task that had been undertaken, or the outstanding success of its preliminary efforts. However, said Dr. Cary, "the ultimate effectiveness of the Committee will be determined by the extent to which it receives support from the rank and file of all practicing physicians."

THE CLINICAL PATHOLOGIST

MEMORANDUM SENT TO THE BOARD OF TRUSTEES OF THE AMERICAN MEDICAL ASSOCIATION

It is not usually considered that clinical pathology is one of the youngest branches of medicine. The first pathologist who devoted full time to the subject, Dr. Frederic Sondern, of New York, is still alive and is an honored member of the American Medical Association, having served on many of its important committees. Previous to twenty-five years ago, one could scarcely speak of clinical pathology as a specialty since so few men had given particular thought or study to the subject and since there was no organization of the subject in the form of private practice.

Those men who had a particular leaning toward the application of pathology to clinical medicine were in a large part members of the American Association of Pathologists and Bacteriologists, which society was developed along rather broad scientific concepts and which has constantly disclaimed any particular interest in the economic problems relating to the practice of pathology.

It was under these conditions that the American Society of Clinical Pathologists was organized in 1921. The charter members desired the society to serve as an organization for those men who were primarily interested in clinical pathology and its application to the actual practice of medicine. They fully recognized the importance and desirability of having men join

the society whose interests were also in research. In addition to these aims, it was the intention of the group to place clinical pathology on a basis equal to that of any other specialty in medicine, both professionally and economically.

The American Society of Clinical Pathologists early took consideration of the problem of laboratory technicians. It has established the Registry of Medical Technologists, in which nearly 9,000 technicians are now registered, and has established the standards of proficiency and standard curriculums for approved training schools. This is now a cooperative enterprise of the American Society of Clinical Pathologists and the Council on Medical Education and Hospitals of the American Medical Association. The Society took the initiative in establishing the American Board of Pathology. The Society has sponsored annual seminars in tumor diagnosis and frequent hematologic seminars, and it has also sponsored and financed the Tumor Registry at the Army Medical Museum. This unique wealth of material is now available to any physician for study. It inaugurated the Committee on the Evaluation of Serodiagnostic Tests for Syphilis in cooperation with the United States Public Health Service. The Society now has a membership of 640 physicians, which is an extremely large proportion when it is

realized that probably not over 900 men could qualify as pathologists in this country. A number of these pathologists are engaged exclusively in teaching and institutional work.

Some of the principal purposes of the American Society of Clinical Pathologists are:

1. To improve the status of pathologists in hospitals, with the hope that the practice of medicine in this field by hospitals will be suppressed;

2. To influence practitioners of medicine to utilize the clinical pathologist as a consultant and to recognize that he has special training, knowledge and skill which most clinicians do not possess and which is essential for the proper care of patients;

3. To educate the public to the usefulness in the community of the functions of physicians who specialize in clinical pathology;

4. To define the functions of state board of health laboratories and restrict their practice to purely public health fields;

5. To make the practice of pathology sufficiently remunerative so that it will attract young, well trained men into the field, that pathology may develop its full usefulness.

For many years pathologists have clearly recognized that their field of medicine is the one through which most forms of corporate medical practice, state medical practice and many forms of socialized medicine would enter. Like roentgenology, many of the tools utilized by the pathologists are mechanical devices and the nature of the specialty demands the hands of many technical assistants. This has made it possible to use the field of pathology as an entrance for many schemes which have retarded the development of this specialty so that it has not reached the same degree of development as have many other medical specialties. To be sure, the origin of this difficulty took place before physicians began to specialize in this field. The early recognition of the paramount importance of the laboratory in the control of contagious diseases, and the obligation of states and the federal government in their control, automatically placed a certain part of the field of laboratory medicine in the hands of the state departments of health.

Pathologists today do not doubt the necessity for the control of contagious diseases by state and federal governmental agencies, nor do they object to the proper expansion of governmental laboratories in fields in which public health control measures are involved. On the other hand, pathologists do oppose the improper expansion of this service to include the medical care, from a laboratory standpoint, of individuals whose illness is not of public health concern and where services are rendered without regard to the ability of the patient to pay for such services and are rendered at taxpayers' expense. No one has any quarrel with provisions for laboratory service to those unable to pay, but one may here even question the premise that this service is always best rendered by a state board of health laboratory. The results of the studies of the Committee on the Evaluation of Serodiagnostic Methods for Syphilis reveal that 62 per cent of state department of health laboratories in this country are as yet incapable of performing satisfactorily tests for syphilis. Pathologists oppose the practice of pathology by laymen. It has previously been established that pathology is a medical specialty, now recognized as such by the American Medical Association, and its practice by any one not licensed to practice medicine is not only detrimental ultimately to the public but is actually illegal.

It is heartening to pathologists to observe the zeal with which the American Medical Association has fought against laymen who practice medicine in opposition to other branches of medicine and has even invited litigation by them. If the practice of pathology by those unlicensed to practice medicine continues to grow as it has in the past, physicians will be forced to abandon the field. The growth of pathology demands that capable young physicians enter the field and, unless satisfactory inducements are provided, few will elect this specialty.

While the expansion of the functions of the state board of health laboratories has been realistically studied for many years by the American Society of Clinical Pathologists, their importance in curtailing the work of private practitioners of pathology has been emphasized by recent developments of the program of the United States Public Health Service. The situation has become more acute recently by the issuance of Supplement 10 of the United States Public Health Service, entitled "Control of the Venereal Diseases in the United States." It is no secret

that the government exercises strong control on the actions of state boards of health, and through its regulations and methods of approval of grants-in-aid and appropriations to these boards it can and does enforce its desires on the methods and services of such boards.

Supplement 10 at first reading does not contain conflicting statements in regard to laboratory service, and evidence indicates that most state boards of health and certainly nearly all officials of the federal government are interpreting paragraphs 2 and 3 of section XV on the basis of paragraph 3:

2. The state laboratory and any local laboratory receiving funds under this act shall provide laboratory services for the venereal diseases on the same basis as such service is provided for other communicable diseases. No state department of health shall be entitled to receive payments under this act unless such laboratory services are provided within that state.

3. Free diagnostic and treatment facilities shall be provided by all health departments or clinics receiving funds under this act for (a) the diagnosis and emergency treatment of all patients who apply; (b) all patients referred by a private physician either for continued treatment or for consultative advice and opinion; and (c) all patients unable to afford private medical care. The determination of the ability of patients to pay for private medical care shall be the responsibility of the state or local health department or constituted welfare agencies within these areas. Clinics collecting fees from semi-indigent patients shall not receive assistance under this act unless such fees are used solely by the venereal disease clinic for improvement of diagnostic and therapeutic services rendered therein.

If this interpretation is generally followed, it will result in such a curtailment of private and hospital pathologic laboratories that many will have to be abandoned and the curious phenomenon will result of pathologists contributing taxes to force themselves out of earning a livelihood. This is not, however, the major consideration. The loss of widely distributed pathologic laboratories and their services would be a definite detriment to all concerned, including the patient. If it be established that the state board of health laboratories can take over this branch of medicine, there is no logical reason why it cannot and will not invade all branches of medicine. Pathologists have from time to time called attention to this fact and it is with some satisfaction, yet apprehension and regret, that this prediction is beginning to be realized by all physicians.

Owing to the efforts of certain members of the Kansas State Board of Health, a new interpretation of these quoted paragraphs in Supplement 10 has been exposed and a letter from Dr. R. A. Vonderlehr, Assistant Surgeon General in charge of the Division of Venereal Diseases, has approved this new interpretation. This interpretation follows the literal wording of paragraph 2, which places the laboratory service for the control of venereal diseases on the same basis as such services for other communicable diseases. Since state laboratories generally have extended these services to embrace a great variety of laboratory tests, without regard to the ability of persons to pay, at first sight this new interpretation appears not to alter current practices of state board of health laboratories. Nevertheless, it provides a means whereby a radical correction of the state board of health practices is now possible and feasible. The Kansas State Board of Health acted immediately following the approval of this policy by the United States Public Health Service. The board passed the following resolution:

The Kansas State Board of Health hereby instructs the state laboratories to furnish laboratory service for diagnosis of all communicable diseases at public expense to all state and county board of social welfare clients, at public expense to all state and county board of social welfare clients, at public expense to all state and county board of social welfare clients; to all inmates or patients of social types of public assistance clients; to all inmates or patients of federal, state, county, or municipal institutions and homes; and to all other residents of the state of Kansas who find it difficult or impossible to pay the costs of laboratory service of this kind in the usual and customary manner.

In order to assist in the provision of this service, the Board has approved the following request form, which will be placed in use effective Jan. 2, 1940:

REQUEST FOR SPECIMEN EXAMINATION BY THE KANSAS STATE BOARD OF HEALTH LABORATORY

I do hereby certify that it will be difficult or impossible for of (county) (name) (street) (city) to pay for this examination in the usual and customary manner. I request therefore that this test be made for me without charge by the Kansas State Board of Health Laboratory.
(Physician's signature).....

(Technical data in regard to test on reverse side of card.)

The Board also instructs the State Laboratories to provide laboratory service, at public expense and without requirements of request forms, to all county and city health officers, all employees of the Kansas State Board of Health and all staff members of federal, state, county and municipal institutions and homes who desire to utilize the services of the state laboratories in conjunction with their official duty.

The Board feels, however, that it should not provide services of this kind at taxpayers' expense to persons able to provide for themselves. Since for practical reasons the Board must leave the determination of this question to the physicians of the state, it respectfully requests the cooperation of all physicians in making certain that state laboratory services are furnished only to persons within the above approved categories. All regulations in conflict herewith are revoked.

After the adoption of this resolution by the Kansas State Board of Health, the following letter was sent to Dr. F. P. Helm, secretary of the State Board of Health of Kansas, by Dr. R. A. Vonderlehr, Assistant Surgeon General, United States Public Health Service:

Federal Security Agency
U. S. PUBLIC HEALTH SERVICE
Washington, D. C.

Nov. 29, 1939.

Dr. F. P. Helm, Secretary
State Board of Health
Topeka, Kansas
Dear Doctor Helm:

I have your letter of November 23d and the copy of the resolution which was passed by the Kansas State Board of Health at a special meeting held November 23d.

The action taken by the Board places laboratory tests for venereal diseases in the state of Kansas on the same basis as such services are provided for other communicable diseases, and meets the letter of the Surgeon General's Regulations Governing Allotments and Payments to the States for Venereal Disease Control Activities for the Fiscal year 1940, as set forth in paragraph 2, section XV.

Sincerely yours,
R. A. VONDERLEHR,
Assistant Surgeon General,
Division of Venereal Diseases.

Many plans have been proposed to curtail the expansion of state laboratories, but in the opinion of the Executive Committee of the American Society of Clinical Pathologists the resolution adopted by the Kansas State Board of Health and approved by the United States Public Health Service is the most practical plan yet presented, and, if followed in the spirit in which it was adopted, it would do much to clarify the relation of private practitioners of pathology to state board of health laboratories.

The American Society of Clinical Pathologists respectfully requests the Board of Trustees of the American Medical Association to extend its good offices in suppressing the practice of laboratory medicine by laymen and to use its strong influence toward establishing a proper relationship between state board of health laboratories and physicians who practice pathology, using as a basis for action the resolution recently passed by the Kansas State Board of Health. Such an effort on the part of the Board of Trustees of the American Medical Association would be consistent with its activities with regard to the practice of other specialties in medicine.

L. W. LARSON, Bismarck, N. D.,
President.
T. B. MAGATH, Rochester, Minn.,

Secretary-Treasurer.
W. M. SIMPSON, Dayton, Ohio,
Member of Special Committee.

GRADUATE MEDICAL EDUCATION

A PROGRESS REPORT OF THE FIELD STUDY ON GRADUATE MEDICAL EDUCATION IN THE UNITED STATES
BEING CONDUCTED BY THE COUNCIL ON MEDICAL EDUCATION AND HOSPITALS

GEORGIA

During the past, several agencies in Georgia have been interested in graduate medical education. At times these groups have carried on their work independently and at other times they have participated in cooperative programs. As the history of these groups is interrelated, the complete story of their independent efforts is best told separately with comments on combined efforts that have been successful.

EMORY UNIVERSITY SCHOOL OF MEDICINE

In 1919 the Georgia Department of Public Health in cooperation with Emory University School of Medicine instituted an annual one week clinic, which was devoted primarily to lectures and conferences on venereal diseases. In 1922 the Alumni Association of the school joined in this enterprise and added the clinics in general medicine and surgery. These clinics have continued to the present and are now given during the week preceding commencement.

In July 1926 the school of medicine gave a two weeks course of instruction for physicians in general medicine and surgery. After this course had been given for a number of years, it was finally discontinued. In 1930 the departments of medicine and surgery cooperated with the Negro physicians of Atlanta in organizing one medical and one surgical conference for them each month. Negro physicians participated actively in these conferences. Patients from the Negro division of the Grady Hospital were presented with their case histories, which were discussed by members of the medical faculty. Special emphasis was placed on the diagnostic and therapeutic procedures available in the hospital. These conferences were continued for three years and were apparently well attended by about half of the Negro physicians of the city. They have since been discontinued.

In June 1930 the department of obstetrics and gynecology offered a six day postgraduate course to Negro physicians of the state. The Julius Rosenwald Fund aided by providing traveling expenses and a stipend for those who enrolled. About fifty Negro physicians from various parts of the state attended. In August 1931 a similar six day course was given under the same auspices and was as well attended.

In July 1935, with the financial cooperation of the Julius Rosenwald Fund, the department of pediatrics offered a five

day course to a limited number of Negro physicians of the state. Those who attended were given a daily allowance. This effort was repeated in 1936 and the attendance was again limited to twelve physicians.

UNIVERSITY OF GEORGIA SCHOOL OF MEDICINE

In a report on extension courses offered to practicing physicians in Georgia during the 1924-1925 session, the dean of the school of medicine stated that it was the purpose of the school to put its facilities at the disposal of the alumni and of all other physicians in the state who cared to avail themselves of them. This was part of the university's plan to stimulate statewide interest in the school of medicine. Clinics were conducted also in a number of towns conveniently located throughout the state. Members of the medical school faculty gave lectures preceding these clinics, and physicians practicing in the locality participated in the conduct of the clinic. About 1928 Emory University School of Medicine joined with the University of Georgia in the conduct of these clinics. Arrangements were made whereby members of the faculties of both schools participated.

In 1932 the state board of health assumed the responsibility for arranging these extension programs. In 1934 the Extension Division of the University of Georgia assumed sponsorship of the clinics on behalf of the university's school of medicine. At this time it was decided to include the Medical Association of Georgia, so as to indicate to the profession throughout the state that the association approved of the program. The state department of health requested county medical officers to arrange meeting places. At this time the state was divided conveniently, with each school responsible for its own geographic area.

In 1935 the School of Medicine of Emory University was not represented in the extension clinics. In 1936 it was decided that the initiative for future graduate clinics must come from the communities in which they were to be held. A committee was appointed by the Medical Association of Georgia to assume this responsibility and the state department of health discontinued initiating plans for such clinics.

Each year since 1936 the University of Georgia, with the assistance of the Julius Rosenwald Fund during the first two years, has given a one or two weeks course in general medicine, surgery, pediatrics and obstetrics for Negro physicians at the

medical school. Lectures, ward rounds and clinics for small groups, clinical pathologic conferences and x-ray demonstrations are included. In 1939 patients were assigned to student physicians for the first time. Members of the faculty of medicine supervised the instruction and assumed responsibility for the course. Attendance has ranged from twenty-five to fifty. Additional instruction has been requested in essential laboratory procedures, physical diagnosis and clinical pathology.

OTHER GRADUATE ACTIVITIES

In January and February and in October and November 1939 the state department of public health held a series of two meetings in each of nine and ten localities of the state respectively. The meetings were given under the auspices of the local county medical society in each section. Four speakers who were members of the department of public health conducted the programs. Subjects included were laboratory aids, obstetrics, tuberculosis, venereal diseases including congenital syphilis, and cancer. Three hundred physicians practicing in ninety-two counties attended the first series and 217 from seventy-one counties attended the second series.

The Atlanta Graduate Medical Assembly held its first annual four day session in 1938. This assembly is sponsored by the Fulton County Medical Society and is administered by an executive committee of this society. The first year the county society underwrote the program, but since then this has not been necessary. From fourteen to sixteen guest speakers are invited each year to speak on subjects of general interest. The lectures and exhibits are held in a local hotel. A registration fee of \$5 is charged; interns and medical students are admitted without charge. Commercial exhibits aid in financing. Total attendance has ranged from 400 to 580.

MEDICAL ASSOCIATION OF GEORGIA

At the 1939 annual session of the Medical Association of Georgia, the committee on postgraduate medical education submitted a report which was essentially as follows:

It is felt that postgraduate instruction, in order to be effective, should be conducted in connection with the two medical schools of the state. It is thought that such instruction should be given to small groups or to individuals by special arrangement. Individual instruction in hospital wards might include a study of several subjects. Small group instruction is believed to be more desirable for student physicians than didactic talks to large groups. Four postgraduate centers might be established where clinical facilities are known to be adequate. Occasionally extension work in other communities might be worthwhile. The necessity of the state association appropriating adequate funds for financing a state-wide program is emphasized.

The House of Delegates of the Medical Association of Georgia in July 1939 published the following statement on postgraduate study:

As there are several agencies in the state engaged in postgraduate work and no cooperation between them, all state agencies are requested to coordinate their work and organize their activities under one group.

In January 1939 the chairman of the postgraduate committee, Dr. G. Lombard Kelly, notified all county medical societies in Georgia of the action of the house of delegates at its 1936 session, which called for the initiation of extension teaching programs by county societies. The chairman reported that the state medical association was prepared to conduct courses and hold clinics in various parts of the state whenever requested to do so. It had been recommended earlier that programs should center around local hospitals, utilizing patient clinics for demonstration of new diagnostic, including laboratory, procedures. Under this plan, instructors would not be limited to members of faculties of medicine.

Of the 2,756 physicians licensed in the state, 1,938 were members of the Medical Association of Georgia.

MEDICAL LEGISLATION

MEDICAL BILLS IN CONGRESS

Change in Status.—S. 2284 has been reported to the House, with recommendation that it pass, proposing to authorize the President to appoint 100 acting assistant surgeons for temporary service in the Medical Corps of the Navy.

Bills Introduced.—S. 3350, introduced by Senator McCarran, Nevada, and H. R. 8437, introduced by Representative White, Idaho, propose to authorize the President through the agency of the Director of the Geological Survey, Department of the Interior, to provide for employing unemployed citizens in the discovery and development of the mineral resources of the public lands of the United States and to provide for furnishing the persons so employed with such subsistence, clothing, medical attendance, hospitalization, transportation if deemed expedient, and cash allowance, as may be necessary during the period they are so employed. S. 3323, introduced by Senator McNary, Oregon, proposes to provide pension benefits for certain Spanish-American War veterans equivalent to those granted to Civil War veterans. S. 3365, introduced by Senator Murray, Montana, proposes to amend the Social Security Act in several particulars. One proposed amendment would bring within the coverage of the act service performed in the employ of a corporation, community chest, fund or foundation, organized and operated exclusively for religious, charitable, scientific, literary or educational purposes, or for the prevention of cruelty to children or animals. Corporations, community chests, funds or foundations organized and operated exclusively for religious purposes will remain exempted from the requirements of the act, if the bill should be enacted. H. R. 8233, introduced by Representative Knutson, Minnesota, proposes to amend the Social Security Act so as to exempt from its provisions service performed in the employ of a voluntary employees' benefit association that provides for the furnishing of medical care and/or hospitalization to the members of such association or their dependents. H. R. 8392, introduced by Representative Ferguson, Oklahoma, proposes that the Farm Security Administration shall be established as a permanent agency within

the Department of Agriculture and that the Reconstruction Finance Corporation be directed to make loans to the Secretary of Agriculture not in excess of an aggregate amount of \$150,000,000 for each fiscal year for the purpose of enabling the Farm Security Administration to carry out the duties devolved on it. H. R. 8394, introduced by Representative Ludlow, Indiana, would authorize the Secretary of the Treasury to cause to be struck a medal of appropriate design with suitable emblems, devices and inscriptions to be determined by the Secretary of the Treasury, or a certificate suitable for framing, to commemorate the faithful nursing of the women who voluntarily offered their services and who served with the Army during the influenza epidemic of 1918. H. R. 8439, introduced by Representative Havenner, California, proposes to authorize a federal appropriation of \$300,000,000 to assist public agencies and nonprofit organizations in safeguarding the health of the nation, not exceeding \$100,000,000 of which is to be devoted to projects for the construction, improvement or operation of hospitals or related facilities. H. R. 8478, introduced, by request, by Representative Rankin, Mississippi, proposes to grant benefits to World War veterans suffering with paralysis, paresis or blindness, or who are helpless or bedridden. H. R. 8493, introduced by Representative Byron, Maryland, proposes to provide pensions, compensation, retirement pay and hospital benefits to certain reserve officers of the Army of the United States. H. R. 8514, introduced by Representative Byrns, Tennessee, proposes to provide for eight-hour shifts for nurses in hospitals on the Canal Zone, Isthmus of Panama.

STATE MEDICAL LEGISLATION

New Jersey

Bills Introduced.—A. 141 provides that in each school district the medical inspector, or the nurse under his immediate direction, shall make eye and ear tests of the pupils of the schools in the district at least once in each school year. The tests must be made with such scientific devices and under such rules and regulations as may be approved and prescribed by

the state board of education. S. 78 proposes an appropriation of \$15,000 to be expended by the state department of health for the purchase and free distribution of antipneumococcic serum for the treatment of persons affected with pneumonia and financially unable to purchase the serum and for determining the type of pneumococci from persons suspected or known to have pneumonia.

New York

Bills Introduced.—S. 927 and A. 1399 propose to amend the education law of New York in relation to the issuance of medical licenses so as to provide that an applicant who meets the requirements of the law as to preliminary and professional education, who presents evidence of successful practice or professional experience satisfactory to the commissioner of education and who presents evidence satisfactory to the commissioner that he has been duly licensed by proper authority in any other state, territory, district or possession of the United States after passing examinations which were equivalent as to subject matter and standards to those of New York at that time may without further examination, on payment of a fee of \$25 and on submitting such further evidence as the commissioner may require, receive from the commissioner in his discretion an endorsement of his license or diploma conferring all rights and privileges of a license issued by the department after examination. S. 1158 and A. 1420, both introduced at the request of the New York State Temporary Commission to Formulate a Health Program, propose to impose, as a condition precedent to medical licensure, an internship requirement of not less than twelve months in a hospital in the United States or Canada approved and registered as maintaining at the time a standard satisfactory to the commissioner of education and the state board of medical examiners. A. 1373 proposes that every physician shall immediately give notice to the health officer of every case of infantile paralysis under his care, the notice to contain such information concerning the case as shall be required by the state commissioner of health. Like notice

must be given by the person in charge of any hospital, dispensary, asylum or other similar public or private institution. The bill also proposes to create in the state department of health a division of infantile paralysis control and the commissioner of health through this division is directed to continue to conduct investigations of the cause, mortality rate, methods of treatment, prevention and cure of infantile paralysis and allied diseases, including the nature and extent of the facilities available in the several counties and cities of the state, for the diagnosis and treatment of these diseases, and is further directed to cooperate with local health authorities, physicians, hospitals, clinics and voluntary associations, in the development of suitable facilities for the diagnosis, treatment and control of infantile paralysis.

Virginia

Bills Introduced.—House Joint Resolution 28 proposes to create a commission consisting of five members, one to be a member of the senate, two to be members of the house of delegates and two to be appointed by the governor from the citizens at large to (a) study rural health conditions in Virginia, (b) study the adequacy and cost of medical and hospital care available to rural people, (c) analyze the various programs for providing clinics and preventive medical service in Virginia in comparison with what is being done in these fields in other states, (d) analyze the applicability of various plans for health, medical and hospital care and insurance to rural Virginia, and (e) recommend ways and means of providing more adequate health, medical and hospital care for rural people in Virginia. In carrying out its functions, the commission is to be authorized to enlist the aid of the Medical Society of Virginia, the Virginia State Dental Association, the Virginia State Department of Health and certain other named agencies and organizations. The commission is to be required to submit its report and recommendations to the governor and to the members of the general assembly on or before July 1, 1941.

OFFICIAL NOTES

THE NEW YORK SESSION

American Physicians' Art Association

The American Physicians' Art Association will hold its annual exhibit, June 9-15, during the time of the annual session of the American Medical Association in New York. The headquarters of the physicians' art association will be located in a booth, which Mead Johnson & Co. has donated, on the third floor of the technical exhibits at the Grand Central Palace on Lexington Avenue. In this booth, which will be 27 by 30 feet with the entire front open, will be placed some of the extraordinary art objects in the exhibit. The booth is number 303A. In addition, the entire top floor—exhibit hall, banquet room, roof gardens, piazzas—of the Belmont-Plaza Hotel, which is across the street from the Waldorf Astoria Hotel, will be turned over to the American Physicians' Art Association. The New York Physicians' Art Club will act as host. The

eighteen California Rhythm Doctors will make a special trip to New York to play at the banquet of the art association at the Belmont-Plaza, Wednesday night, June 12. The members of this orchestra, in addition to being expert instrumentalists, are also singers, comedians and specialty artists. Dr. Hannibal De Bellis, 316 West Eighteenth Street, New York, is chairman of the dinner committee. Many prizes have been donated for the prize-winning exhibits. The \$1 dues for this season should be mailed at once to the treasurer of the association, Dr. Raleigh W. Burlingame, San Francisco Hospital, San Francisco. Details of the exhibit plans and other arrangements may be obtained by writing to the president of the American Physicians' Art Association, Dr. Henry N. Moeller, 327 Central Park West, New York, or to the chairman of the arrangements committee, Dr. Abraham Wolbarst, 114 East Sixty-First Street, New York.

NATIONAL CONFERENCE ON MEDICAL NOMENCLATURE

On March 1, at the Headquarters Office of the American Medical Association, there will be a Conference on Medical Nomenclature designed to bring out discussion on a number of important problems connected with terminology. The program is as follows:

NATIONAL CONFERENCE ON MEDICAL NOMENCLATURE

535 North Dearborn Street, Chicago

March 1, 1940

HAYEN EMERSON, M.D., CHAIRMAN

PROGRAM

1. Trends in Medical Terminology.....Morris Fishbein, M.D.
2. Purposes, Function and Use of Standard Classified Nomenclature of Disease.....George Baehr, M.D.
3. International Nomenclature and the International List of Causes of Death.....Halbert L. Dunn, M.D.
4. A Standard Nomenclature of Operations.....H. Perry Jenkins, M.D.
5. The Adaptation of the Standard Classified Nomenclature of Disease to Hospital Morbidity Reports....E. H. L. Corwin, Ph.D.
6. Punch Cards and Tabulating Methods as Applied to Morbidity ReportsMrs. Stella F. Walker
7. Massachusetts Experience in Reporting Mental Disorders
Neil A. Dayton, M.D.
8. The Classification of Tumors for Clinical Purposes—
Preliminary ReportBowman C. Crowell, M.D.
9. Progress Report on Revision of the Standard Classified Nomenclature of Disease.....Edwin P. Jordan, M.D.
10. Problems of Terminology in the Field of Physical MedicineFrank H. Krusen, M.D.
11. Nomenclature and Classification of Allergic Disorders
Samuel M. Feinberg, M.D.
12. Problems of Dermatologic Nomenclature.....Howard Fox, M.D.
13. Terminology in Diseases of the Blood-Forming Organs
Raphael Isaacs, M.D.
14. Diseases of Endocrine Origin.....Elmer L. Seyringhaus, M.D.

Medical News

(PHYSICIANS WILL CONFER A FAVOR BY SENDING FOR THIS DEPARTMENT ITEMS OF NEWS OF MORE OR LESS GENERAL INTEREST: SUCH AS RELATE TO SOCIETY ACTIVITIES, NEW HOSPITALS, EDUCATION AND PUBLIC HEALTH.)

CALIFORNIA

Hospital News.—The psychiatric department of Mount Zion Hospital, San Francisco, announces a series of four discussions on psychotherapy in general practice as follows: March 6, "History of Psychotherapy"; March 13, "Essence of Therapeutic Relationship"; March 20, "Modern Treatment of Neuroses," and March 27, "Psychotherapy in Children."

Clinical Conferences and Postgraduate Courses.—The committee on postgraduate activities of the California Medical Association is sponsoring clinical conferences and postgraduate courses throughout the state under the auspices of the local county medical societies. One will be held in Bakersfield on March 16 by the Kern County Medical Society. At the clinical conferences in Fresno on February 2, 9 and 16 the speakers were Drs. Garnett Cheney, San Francisco, and Edmund W. Butler, San Francisco, on peptic ulcers and pneumonia, respectively; Ernest W. Page, Berkeley, some problems in gynecology and obstetrics, and Clark M. Johnson and Edgar A. W. Wayburn, San Francisco, genito-urinary and venereal diseases and disorders of nutrition, respectively. The Fresno County Medical Society was host. A symposium on gastrointestinal diseases constituted the course before the Santa Cruz, San Benito and Monterey county medical societies, February 1, in Salinas; the speakers were Drs. Fred H. Kruse, David A. Wood and Eric Liljencrantz, San Francisco.

GEORGIA

Emergency Station Dedicated as Memorial to Physician.—An American Red Cross Emergency Station on the Dawson-Shellman highway was dedicated recently to the late Dr. Albert Leroy Crittenden, Shellman, who died, Jan. 25, 1934. Dr. Crittenden once served as president of the Randolph County Medical Society. This is the second of three stations to be dedicated to Randolph County physicians, newspapers reported. The others are in honor of Drs. George V. Moore and Frederick D. Patterson, Cutlibert. Included among the speakers at the Shellman dedication was Dr. Job C. Patterson, Cutlibert, president of the state medical society.

ILLINOIS

Handbook on Pneumonia.—A handbook on pneumonia has been published by the state department of health and is available free to physicians in Illinois who send requests to the department at Springfield or to the committee on education of the Illinois State Medical Society, 30 North Michigan Avenue, Chicago. Prepared by the state advisory committee on pneumonia control, the booklet contains in brief but comprehensive form specific, up-to-date information on the diagnosis and treatment of the pneumonias. The technic of utilizing various therapeutic measures is included.

New Assistant Director of Health.—Dr. Roland R. Cross, Dahlgren, superintendent of the health district in Southern Illinois since 1933, has been appointed assistant director of the Illinois State Department of Health. Dr. Cross graduated at the American Medical College, St. Louis, in 1912. He spent six years in Indian work as a member of the U. S. Public Health Service and served in the World War. He was president of the Jefferson-Hamilton Counties Medical Society in 1931. The position to which Dr. Cross has been appointed has been vacant since 1937, when Dr. Albert C. Baxter, Springfield, present health director, was named acting director of the department.

New Mental Hygiene Post Created.—Dr. Conrad S. Sommer, Chicago, director of the Illinois Society for Mental Hygiene, has been appointed to the newly created post of state superintendent of the division of mental hygiene, the Chicago *Tribune* reports. The new division is in the state department of public welfare and was created on the recommendation of the Institute of Medicine of Chicago. Dr. Sommer has taken a year's leave of absence from the society of mental hygiene. In his new capacity he will supervise medical care and treatment of the 30,000 patients in the ten state mental institutions, and will be responsible to the state alienist. Dr. Sommer graduated at the University of Illinois College of Medicine in

1932. He was resident psychiatrist at the Illinois Research Hospital from 1932 to 1933 and fellow at the Institute for Juvenile Research from 1935 to 1937. For the last three years he has been connected with the Illinois Society for Mental Hygiene and assistant clinical professor of psychiatry at Loyola University School of Medicine.

Chicago

Hospital News.—Dr. Carl J. Wiggers, professor of physiology, Western Reserve University School of Medicine, Cleveland, lectured at Michael Reese Hospital February 6, on "Characteristics and Variations in Normal Heart Sounds." The lecture was under the auspices of the cardiovascular group.

Session on Venereal Diseases.—The venereal disease commission of the Chicago Medical Society has planned a program, February 28, to further its policy of utilizing the clinical material of the Municipal Social Hygiene Clinic. Dr. Bell F. Korman, chief of the department of syphilis in childhood at the clinic, will present an outline of the treatment of syphilis in childhood, with a statistical report of the results of 800 cases and a demonstration of juvenile tabes, dementia paralytica and syphilitic keratitis. Discussions will be offered by Drs. Noel G. Shaw, Isador M. Levin and Harold A. Rosenbaum. The meeting will be held at the social hygiene clinic.

Dr. Irving S. Cutter Honored.—Robert R. McCormick, editor and publisher of the Chicago *Tribune*, has given the property at the northwest corner of Lake Shore Drive and Pearson Street to Northwestern University "for the purpose of establishing and maintaining a fund, the income from which is to be spent for research in the medical school." The fund is to be called the "Irving S. Cutter Fund for Medical Research," in honor of the dean of the medical school, who is also health editor of the *Tribune*. Dr. Cutter has been dean since 1925 and medical director of Passavant Hospital since 1928.

Branch Meetings.—Dr. George K. Fenn discussed "Electrocardiography" before the Southern Cook County Branch of the Chicago Medical Society recently. At a meeting of the Irving Park Branch, January 16, Dr. Frederick H. Falls discussed "Indications and Technic of Cesarean Section." Dr. Italo F. Volini addressed the Jackson Park Branch, January 18, on "The Modern Treatment of Pneumonia." The West Side Branch was addressed by Dr. Joseph F. Jaros, January 18, on "Electrocoagulation." At a joint meeting of the Chicago Medical Society and the Stock Yards Branch, January 18, the speakers were Drs. Bert I. Beverly and Julius H. Hess on "Problems of Adolescence" and "Infant Feeding as We See It Today." The Calumet Branch devoted its January 19 meeting to a symposium on diseases of the stomach. Dr. George E. Wakerlin addressed the Northwest Branch, January 19, on "The Pathogenesis and Therapy of Non-Nephritic Hypertension." Dr. Michael L. Mason discussed "Treatment of Open Wounds" before the South Chicago Branch, January 23.

INDIANA

Society News.—The Fountain-Warren County Medical Society was addressed in Covington, February 1, by Drs. Wemple Dodds, James M. Kirtley and George A. Collett, Crawfordsville, on "Toxemia of Gestation: Its Pathology, Diagnosis and Treatment."—At a meeting of the Dearborn-Ohio County Medical Society in Lawrenceburg, February 1, Dr. Louis P. Stickley, Cincinnati, discussed jaundice.

IOWA

Physician Honored.—The Eldora community award, sponsored by the American Legion post, was presented to Dr. Joseph R. Winnett in January. No public demonstration was made at the time because of the illness of Dr. Winnett. A graduate in 1912 of Drake University College of Medicine, since absorbed by the State University of Iowa College of Medicine, Dr. Winnett has been practicing in Eldora since 1914, except when he was a medical officer at Camp Pike near Little Rock, Ark., during the World War. The award is a silver loving cup.

KANSAS

Society News.—Dr. Ward Darley Jr., Denver, discussed chronic undulant fever before the Shawnee County Medical Society in Topeka, February 5.—The Wyandotte County Medical Society was addressed, February 6, by Dr. Paul M. Krall, Kansas City, on "Essential Factors in the Production of Edema." The society was addressed, February 20, by Drs. Tom R. Hamilton, Kansas City, on "The Thymus Gland (A Study of 7,500 Autopsy Cases)" and William J. Feehan,

Kansas City, spondylolisthesis. At a meeting, January 16, the speakers were Drs. Elden S. Miller and LaVerne B. Spake, Kansas City, on "Complications of Diabetes" and "Diagnosis and Treatment of Deafness" respectively.

MASSACHUSETTS

Personal.—Dr. Ernest M. Morris, formerly health commissioner of Fall River, has been appointed district health officer for all of Hampden County and most of Hampshire County in the western part of the state, with offices in Westfield, it is reported. He succeeds Dr. Charles E. Gill.

Dr. Keefer Named Wade Professor of Medicine.—Dr. Chester S. Keefer, associate professor of medicine, Harvard Medical School, Boston, has been appointed Wade professor of medicine at Boston University School of Medicine, effective on February 1. Dr. Keefer graduated at Johns Hopkins University School of Medicine, Baltimore, in 1922, serving on the staff from then until 1926. The subsequent two years he was a member of the faculty of the University of Chicago, going to Peiping Union Medical College, Peiping, China, in 1928. He was at Harvard from 1930 until his recent appointment. Dr. Keefer succeeds Dr. Reginald Fitz, who plans to engage in private practice.

Society News.—Dr. Edward J. O'Brien Jr., Boston, addressed the Wachusett Medical Improvement Society in Worcester, February 7, on "Surgical Treatment of Prostatic Obstruction."—Dr. Samuel A. Levine, Boston, discussed "A Routine Office Cardiovascular Examination" before the Worcester District Medical Society in December. Among others, Dr. George W. Ballantyne, Worcester, addressed the society, January 10, on "Diabetes and Pregnancy."—Dr. Chester M. Jones, Boston, discussed "Substernal Pain, a Confusing Symptom: Its Clinical Significance" before the Hampden District Medical Society in Springfield, January 23.—Dr. James W. Sever, Boston, will address the Pentucket Association of Physicians March 14 on "Recent Advances in Orthopedic Surgery."

MICHIGAN

Changes in Health Officers.—Dr. Robert F. Hall, Mason, assistant medical director of the health unit in Ingham County, has been appointed in charge of the unit in Bay City. Dr. Lorin E. Kerr Jr., Charlotte, has been named to succeed Dr. Hall in Ingham County. Dr. Hall is the first full time health officer in Bay City, succeeding Dr. George W. Moore, who held the office on a part time basis for fifteen years, it is reported.

Society News.—Dr. James H. Mitchell, Chicago, addressed the Wayne County Medical Society, February 12, on "Differential Diagnosis of the Cutaneous and Mucous Membrane Lesions of Syphilis."—At a meeting of the Jackson County Medical Society in Jackson, January 16, a symposium on "Michigan Medical Service and Medical Welfare Relief" was presented by Dr. Henry R. Carstens, Detroit; Dr. L. Fernald Foster, Bay City; William J. Burns, LL.B., Lansing, and Mr. J. D. Laux, Lansing.

New Building for Dental Research.—The new W. K. Kellogg Foundation Institute for Graduate and Postgraduate Dentistry will be dedicated in Ann Arbor, April 3. The speakers will include Dr. Clarence O. Simpson, St. Louis, whose address will be on radiology. A memorial will be unveiled in honor of Willoughby D. Miller, American dentist (1853-1907). By a series of experiments beginning about 1880, Dr. Miller demonstrated the essential relation between mouth bacteria and decay of the teeth. He showed that a dissolution of the lime salts in dentin was caused by acid elaborated by microorganisms. He produced caries in the laboratory. His work was summarized in a book published in 1890, entitled "Micro-Organisms of the Human Mouth."

MINNESOTA

New Director of School Hygiene.—Dr. Arthur E. Karlstrom has been appointed director of school hygiene and health of Minneapolis. He succeeds Dr. Malvin J. Nydahl, who resigned to become head of the bureau of crippled children, state division of social welfare. Dr. Karlstrom graduated at the University of Minnesota Medical School in 1936.

Society News.—Dr. Erwin R. Schmidt, Madison, Wis., discussed "Peritonitis Secondary to the Appendix" before the Hennepin County Medical Society, Minneapolis, February 5.—Dr. Willard O. Thompson, associate clinical professor of medicine, Rush Medical College, Chicago, gave a Mayo Foundation lecture in Rochester, January 18, on "Hypogenitalism in the Male."

MISSOURI

Physician Honored.—The Dallas-Hickory-Polk County Medical Society held a special meeting and banquet in Bolivar recently to honor Dr. Joseph F. Roberts, Bolivar, on his eighty-ninth birthday. Dr. Roberts has practiced medicine for sixty-seven years, sixty-two of them in Bolivar; he still goes to his office each day, according to the state medical journal. Dr. Homer L. Kerr, Cranc, was toastmaster at the dinner and Dr. James R. McVay, Kansas City, president of the state medical association, gave the principal address. About seventy-five physicians and their friends attended. Dr. Roberts graduated at Missouri Medical College in 1877.

Society News.—Dr. Robert Elman, St. Louis, addressed the Kansas City Academy of Medicine, January 19, on "Surgical Aspects of Protein Metabolism." Dr. Wallace M. Yater, Washington, D. C., addressed the academy, February 16, on "Late Advances in the Study of Diseases of the Blood Vessels."—Dr. George Wise Robinson Sr., Kansas City, addressed the Lawrence-Stone County Medical Society, January 16, on "Newer Methods of Treatment of the Psychoses."—The speakers before the South Central Counties Medical Society in West Plains, January 11, were Drs. George W. Hogeboom, Springfield, on "Changing Trends in the Surgical Treatment of Gallbladder Disease"; Francis B. Camp, Springfield, "Sulfanilamide and Its Derivatives," and William J. Gonorrhea, "Use of Sulfanilamide in the Treatment of

NEW YORK

Eastman Lecture.—Philip E. Smith, Ph.D., professor of anatomy, College of Physicians and Surgeons, Columbia University, delivered the Eastman Memorial Lecture at the University of Rochester School of Medicine on January 23. His subject was interrelationship between the hypophysis and the reproductive system.

Food Poisoning from Sodium Fluoride.—An outbreak of sixty-nine cases of food poisoning at a state institution for adolescent and young adult males on December 26 was traced to contamination with sodium fluoride used to kill roaches. The illness occurred among 143 inmates who had luncheon half an hour earlier than the remaining 488. The onset was sudden, most of the victims having developed symptoms within ten minutes after the meal. Chocolate pudding was immediately suspected and another dessert was substituted for the remainder of the luncheon. None of those who ate later became ill. Samples analyzed in the laboratories of the state department of health were found to contain from 0.1 to 0.3 per cent of sodium fluoride.

New York City

Twenty-Fifth Class Reunion.—The twenty-fifth reunion of the class of 1915 of New York University College of Medicine will be held at Delmonico's, Saturday, May 11. Further information may be obtained from Dr. Henry M. Scheer, 522 West End Avenue, president.

Doctors' Orchestra.—The Doctors' Orchestral Society of New York now has headquarters at the National Hospital for Speech Disorders, through the interest of the medical director, Dr. James Sonnett Greene. The auditorium and other rooms have been placed at the disposal of the orchestra for a permanent home and the first rehearsal was held there on January 18.

Professor Appointed.—Dr. Howard W. Potter, professor of clinical psychiatry, College of Physicians and Surgeons of Columbia University, has been appointed clinical professor in the department of neurology and psychiatry at Long Island College of Medicine. Dr. Potter graduated at Columbia in 1913. He served as assistant physician at Bloomingdale Hospital (now the New York Hospital, Westchester Division) from 1916 to 1920, and at Hudson River State Hospital from 1920 to 1921. From 1921 to 1929 he was clinical director at Letchworth Village, Thiells, and for the next five years was assistant director of the New York State Psychiatric Institute and Hospital. Since 1934 he has been attending psychiatrist at the Neurological Institute and consulting psychiatrist at Nyack, Englewood and Rockland hospitals. He has been president and secretary of the American Association on Mental Deficiency and is a member of various other special societies.

Society News.—Among speakers at a meeting of the committee on cardiac clinics, New York Heart Association, February 27, will be Drs. Thomas H. McGavack on "Changes in Heart Volume in Addison's Disease and Their Significance"; Paul K. Boyer, "Influence of Digitalis on the Electrolyte and

Water Balance of Heart Muscle, and Henry A. Schroeder, "Relation of the Intake of Salt and Water to the Edema of Heart Failure."—Speakers before the New York Pathological Society on January 25 were Drs. David H. Goldstein and Irving Graef, on "The Influence of Sulfanilamide and Sulfapyridine upon the Evolution of Experimentally Induced Pneumococcus Pneumonia in Rats," and Cornelius P. Rhoads, on "Aplastic Anemia."—Dr. Henry L. Jaffe addressed the New York Roentgen Society, January 15, on "Findings in Cases Generally Misinterpreted as Cortical Bone Abscess or Selecting Osteomyelitis of Long Bones."—A symposium on "Experimental and Clinical Phases of Sex Hormone Therapy" was presented before the section of genito-urinary surgery of the New York Academy of Medicine, January 17, by Drs. James F. McCahey, Philadelphia; Walter M. Kearns, Milwaukee, and Norris J. Heckel, Chicago.—Dr. Aaron S. Blumgarten addressed the New York Endocrinological Society, January 24, on "Critical Evaluation of Modern Hormone Therapy."—A symposium on operative treatment of lesions of the chest was presented before the New York Surgical Society on January 24 by Drs. Harold Neuhof, Arthur S. W. Touroff, Arthur H. Aufses, William De W. Andrus and George J. Heuer.

OHIO

Portrait of Dr. Todd.—A portrait of the late Dr. T. Wingate Todd, professor of anatomy at Western Reserve University School of Medicine, Cleveland, was recently presented to the library of the department of anatomy by the Charles Bolton Fund. Birdsall Holly Broadbent, D.D.S., director of the fund, made the presentation on Dr. Todd's birthday, January 15, and President Winfred C. Leutner, LL.D., accepted it. The portrait was painted by Dr. Erich von Baeyer, fellow in roentgenology at University Hospitals.

University News.—The John and Mary R. Markle Foundation has made a grant of \$6,000 to Western Reserve University School of Medicine, Cleveland, to support the research of Dr. Claude S. Beck, associate professor of surgery, on methods of revascularizing the heart after coronary obstruction. The National Research Council made a grant of \$1,250 for a study of human ovulation under the direction of William W. Greulich, Ph.D., professor of physical anthropology and anatomy and director of the Brush Foundation.

New Dean at Cincinnati.—Dr. Stanley E. Dorst, associate professor of medicine and assistant dean of the University of Cincinnati College of Medicine since 1937, has been appointed dean to succeed the late Dr. Alfred Friedlander. He has been acting dean since the death of Dr. Friedlander in May 1939. The new appointment carries with it the positions of chief of staff of the Cincinnati General Hospital and director of the Christian R. Holmes Hospital. Dr. Dorst graduated at Cincinnati in 1923 and became a member of the faculty in 1926.

Personal.—Dr. Clyde L. Smith, Fremont, has been named city health commissioner to succeed Dr. Edgar L. Vermilya, who had served thirty-one years.—Dr. William F. Lyons, Coshooton, was recently appointed city health commissioner to succeed Dr. Jacob D. Lower.—Dr. Joyce I. Hartman has resigned as supervisor of medical inspection in Cleveland schools to devote his time to private practice.—Dr. Carle W. Beane, West Manchester, has been appointed health officer of Preble County to succeed Dr. James I. Nisbet, Eaton, resigned.

Ohio State Annual Assembly.—The Seventh Post-Collegiate Assembly of the Ohio State University College of Medicine, Columbus, will be held all day March 29 and around table discussions will be held all day March 30. At noon there will be an alumni reunion luncheon in honor of the new president of the university, Howard L. Bevis, S.J.D. The guest speakers will be:
Dr. Robert M. Zollinger, Boston, Surgical Problems of the Gallbladder and Extrahepatic Bile Ducts.
Dr. Lee C. Gatewood, Chicago, Indications for Surgical Intervention in Peptic Ulcer from the Standpoint of the Internist.
Dr. George E. Rockwell, Cincinnati, Active Immunization to Tetanus by Means of Tetanus Toxoid.
Dr. Roll H. Markwith, Columbus, Survey of Ohio Public Health Situation.
Dr. John H. Warvel, Indianapolis, Protamine and Other Slow Acting Insulins and Their Clinical Application.
Dr. Charles W. Mueller, Brooklyn, Diagnosis and Treatment of Placenta Praevia.
Dr. John H. J. Upham, dean of the college of medicine, will present "An Interpretation of Current Research at Ohio State University."

WISCONSIN

Personal.—Dr. Michael Kasak, acting medical director of the Milwaukee County Asylum for Chronic Insane and the medical director of the Milwaukee County Hospital for Mental Diseases, was made director from 1925 until the resignation of Dr. Albert F. Young, medical director and superintendent, in January 1939 and since that time has been acting head of the two institutions.

Philadelphia

Hospital News.—The Jewish Hospital has opened a department of endocrinology with Dr. Nathan Einhorn as chief and Dr. Leonard G. Rowntree as consultant.

Potter Memorial Lecture.—Dr. Irvin Abell, Louisville, Ky., delivered the William Potter Memorial Lecture at Jefferson Medical College, February 14. His subject was "The Spirit of Medicine."

Society News.—Dr. Marvin Pierce Rucker, Richmond, Va., addressed the Obstetrical Society of Philadelphia, February 1, on "Toxemias of Pregnancy."—Dr. Tom Douglas Spies, Cincinnati, delivered the forty-sixth Mary Scott Newbold Lecture of the College of Physicians of Philadelphia, February 7, on "The Vitamin B Deficiencies."—Dr. Edward B. Krumhaar addressed the Pathological Society of Philadelphia, February 8, on "The Present Status of Hodgkin's Disease" and Dr. George C. Griffith presented a case of Hodgkin's disease with cardiac involvement.

SOUTH DAKOTA

Personal.—Dr. Antony Triolo, Rapid City, has been appointed director of the division of maternal and child health in the state health department.—Dr. George H. Stidworthy, Deersfield, was honored at a community banquet recently in recognition of his forty years of service.

TEXAS

Twelfth Clinical Conference in Dallas.—The twelfth annual spring clinical conference of the Dallas Southern Clinical Society will be held at the Hotel Adolphus, Dallas, March 11-14. The guest speakers, who will deliver several addresses each, will be:

Dr. Marion A. Blankenhorn, professor of medicine, University of Cincinnati College of Medicine.
Dr. Chester S. Keeler, Wade professor of medicine, University of Medicine, Chicago.
Dr. Warren H. Cole, professor of surgery, University of Cincinnati College of Medicine.
Dr. Clay Ray Murray, associate professor of surgery, University of Illinois College of Physicians and Surgeons, New York.
Dr. Tracy B. Mallory, assistant professor of pathology, Harvard Medical School, Boston.
Dr. John W. Harris, professor of obstetrics and gynecology, University of Wisconsin Medical School, Madison.
Dr. Frank E. Adair, associate professor of clinical surgery, Cornell University Medical College, New York.
Dr. Walter A. Fandler, clinical associate professor of surgery, University of Minnesota Medical School, Minneapolis.
Dr. Frank E. Stevenson, associate professor of pediatrics, University of Cincinnati College of Medicine.
Dr. Meredith F. Campbell, professor of urology, New York University College of Medicine.
Dr. Parker Heath, professor of ophthalmology, Wayne University College of Medicine, Detroit.
Dr. Millard F. Arbuckle, assistant professor of clinical ophthalmology, Washington University School of Medicine, St. Louis.

Society News.—Dr. Loyal Davis, Chicago, addressed the Medical Society of Milwaukee County, January 12, on neurologic surgery.—Dr. John A. Bigler, Highland Park, Ill., addressed the University of Wisconsin Medical Society, Madison, January 12, on "Scarlet Fever, the Dick Test and Hemolytic Streptococcus Throat Cultures."—Dr. Matthew N. Federspiel, Milwaukee, addressed the Brown-Kewaunee Door Counties Medical Society in Green Bay, January 11, on "Fractures and Mutilations of the Face."—Dr. Harold E. Burnett, Madison, addressed the Barron-Washburn-Sawyer-Burnett Counties Medical Society, Rice Lake, January 2, on "Cardiac Arrhythmia."—At the annual meeting of the Milwaukee Society of Clinical Surgery, January 30, the speakers were Drs. Karl Schlaepfer, retiring president, on "Short Wave in Surgery"; Lemuel D. Smith, incoming president, "The Mechanics of Fracture," and Stanley J. Seeger, "Treatment of Burns."—The Wisconsin Tuberculosis Society was recently organized with Dr. William H. Oatway Jr., Madison, as president and Arthur A. Pleyte, Milwaukee, as secretary. The first meeting was held on January 24 in Madison.

GENERAL

Annual Meeting of Nutrition Institute.—The American Institute of Nutrition will meet in New Orleans, March 13, at the Jung Hotel. Papers on current research in nutrition will be presented at meetings during the day and a symposium on "Nutrition for the Higher Health" will form the program for an evening meeting. Henry C. Sherman, Ph.D., New York, president of the institute, will preside at the symposium and the speakers will be:

- Elmer V. McCollum, Ph.D., Baltimore, The Problem of Promoting Better Nutrition.
- Dr. John B. Youmans, Nashville, Tenn., The Assessment of the Nutrition of Populations.
- Dr. Tom Douglas Spies, Cincinnati, Pellagra and Associated Deficiency Diseases as a Medical and Public Health Problem.
- Hazel K. Stiebeling, Ph.D., Washington, D. C., Dietary Levels in the United States.

Southeastern Surgeons to Meet.—The eleventh annual assembly of the Southeastern Surgical Congress will be held at the Tutwiler Hotel, Birmingham, Ala., March 11-13. Among the speakers will be:

- Dr. James K. McGregor, Hamilton, Ont., Dysfunction of the Thyroid Gland as a Cause for Premature Old Age.
- Dr. Kenneth K. Sherwood, Seattle, Classification and Treatment of Chronic Arthritis.
- Dr. Louis A. Buile, Rochester, Minn., Management of Anal Fistulas in Office and Hospital.
- Dr. George M. Curtis, Columbus, Ohio, The Rationale of Splenectomy in the Treatment of Certain Anemias.
- Dr. Stuart W. Harrington, Rochester, Minn., Surgical Treatment of Calcified Constricting Pericardium.
- Dr. Roy D. McClure, Detroit, Modern Treatment of Burns.
- Dr. George T. Pack, New York, Diagnosis and Treatment of Malignant Tumors of the Skin.
- Dr. Edwin G. Ramsdell, New York, Prevention of Wound Disruption.
- Dr. Roy B. Henline, New York, Prostatic Disease, with Special Reference to the Various Causes and Types as Well as Their Treatment.
- Dr. Robert H. Herbst, Chicago, subject to be announced.
- Dr. Stanley J. Seeger, Milwaukee, Pediatric Surgical Problems.
- Dr. James M. Mason, Birmingham, will deliver the C. Jeff Miller Memorial Lecture.

"Foundation Prize" in Obstetrics and Gynecology.—Announcement is made of the annual "Foundation Prize" of \$150 to be awarded by the American Association of Obstetricians, Gynecologists and Abdominal Surgeons. Eligible contestants shall include only (a) interns, residents or graduate students in obstetrics, gynecology or abdominal surgery, and (b) physicians (with an M.D. degree) who are actively practicing these specialties. Manuscripts must be presented to the secretary of the association before June 1 under a nom de plume together with a sealed envelop bearing the nom de plume and containing the name and address of the contestant. Manuscripts must be limited to 5,000 words and must be typewritten in double spacing on one side of the sheet. Ample margins should be provided. Illustrations should be limited to such as of the thesis and the illustrations are to be submitted. The successful thesis will become the property of the association, but this provision does not interfere with publication in the journal of the author's choice. The award will be made at the annual meetings of the association, at which time the successful contestant must appear in person to present his contribution as a part of the regular scientific program, in conformity with the rules of the association and he must meet all expenses incident to the presentation. The secretary is Dr. James R. Bloss, 418 Eleventh Street, Huntington, W. Va.

Activities of Veterans' Administration

During the fiscal year ended June 30, 1939, there were 165,576 admissions of United States veterans to hospitals and a daily average of 49,147 patients of all types under treatment, according to the annual report of the Administrator of Veterans' Affairs.

The hospital load at the end of the year was 54,117, an increase of about 6 per cent over the preceding year. More than 77 per cent of these veterans were receiving treatment for disabilities not of service origin. Of the total patient load, 48,527 patients were World War veterans. More than 64 per cent were in hospitals in their home states.

The hospital load at the end of the year was 54,117, an increase of about 6 per cent over the preceding year. More than 77 per cent of these veterans were receiving treatment for disabilities not of service origin. Of the total patient load, 48,527 patients were World War veterans. More than 64 per cent were in hospitals in their home states.

According to types of illness they were divided as follows: tuberculosis 9.2 per cent, neuropsychiatric diseases 57.68 per cent, general medical and surgical conditions 33.12 per cent. This distribution is in marked contrast to that of 1923, when 41 per cent were ill of tuberculosis, 39 of neuropsychiatric diseases and 20 of general medical and surgical conditions.

The number of admissions for 1939 was the highest for any fiscal year to date, the administrator reported, and more than 92 per cent were for non-service connected disabilities. Admissions by types of diseases were as follows: pulmonary tuberculosis 11,268, mental diseases 9,372, other neurologic disorders 13,240, and general medical and surgical diseases 131,696.

There were 221,509 patients under hospitalization during the year, an increase of 10 per cent over 1938. Of these 218,621 were United States veterans; the remainder included 1,689 members of the Civilian Conservation Corps and Works Progress Administration, 202 veterans of countries allied with the United States in the World War and 741 miscellaneous beneficiaries.

Of the veterans, 164,760 were discharged after an average of 72.4 inpatient days. About 78 per cent of them had been under treatment for general medical and surgical conditions, 15 per cent for neuropsychiatric diseases and 7 per cent for pulmonary tuberculosis. There were 10,880 deaths, including 7,365 among patients under treatment for general conditions, 1,947 for tuberculosis and 1,568 for neuropsychiatric diseases. About 37 per cent were caused by diseases of the circulatory system, including organic heart disease, and approximately 34 per cent by malignant tumors and diseases of the digestive system.

Veterans present in domiciliary status under control and jurisdiction of the Veterans' Administration totaled 15,426, an increase of 1,172 over the preceding year. General medical and surgical conditions accounted for the disabilities of 10,644 of those under domiciliary care, neuropsychiatric diseases for 4,461 and tuberculosis 321.

At the end of the fiscal year the Veterans' Administration was operating hospital facilities at eighty-four locations in forty-five states and the District of Columbia, with a capacity of 54,779 beds, an increase of 2,788 over 1938. In addition the administration was using 2,748 beds in other government hospitals. There were 16,345 beds set aside for domiciliary care. Construction in progress at the time of the report was to add 9,710 beds, and two other projects providing 206 beds were completed in June, though the beds were not available until after the end of the fiscal year, according to the report. New construction for which funds were available but which had not been placed under contract by June 30 was to provide 1,127 hospital and 465 domiciliary beds. During the twenty years since the first law was passed in 1919, a total of \$200,044,766 has been made available for construction of facilities for veterans.

The net operating expense for all facilities for 1939 was \$53,205,919.47. The per diem cost of operation was \$2.68 for all types of cases. For tuberculosis the cost was \$3.97, for general conditions, \$3.59 and for neuropsychiatric diseases \$1.90.

The administration made a total of 1,127,162 physical examinations for outpatient purposes and furnished 1,079,663 outpatient treatments. Two per cent of the examinations and 9 per cent of the treatments were dental.

The report points out that the administration gives continuous study to introduction of new diagnostic and treatment methods, to renovation or replacement of unserviceable equipment and to the training of personnel. Two special units are considered of particular importance: the cardiovascular unit at the Diagnostic Center in Washington, D. C., and the tumor research unit at Hines, Ill., both of which are conducting important research.

Jan. 20, 1940.

Medical Students to Return to London

Most of the London medical schools which were evacuated when war began are bringing back as many students as possible. The minister of health has decided that he can no longer pay for the board and lodging of students who have been attached as dressers to the hospitals prepared around London for the reception of casualties which have not materialized as was expected. But later on if the students should be required to assist in the treatment of casualties he may again pay for their board and lodging. The number who return to London depends on how many can be satisfactorily taught with the number of hospital beds now available in London. The London teaching hospitals are still compelled to reserve one third of their beds for possible civilian casualties, and in some the remaining hospital beds will not be adequate for the clinical teaching of the students. On the other hand, in most cases the education of students billeted at the hospitals in the country suffers. The arrangements for such teaching have been organized for generations at the medical schools of the London hospitals and cannot be reproduced in the country hospitals temporarily organized for the treatment of the casualties of air raids.

The Control of Puerperal Sepsis

The Ministry of Health has issued a memorandum on the control of puerperal fever because the increased knowledge gained during recent years provides a firmer basis for action than has been available heretofore. Yet this knowledge is not being fully applied. It has been shown that the most dangerous puerperal infection—that by hemolytic streptococci—is rarely if ever due to latent infection of the vagina before parturition. It is brought from outside sources at the time of confinement or soon after. The streptococci which give rise to puerperal fever belong to the same group as those responsible for scarlet fever, tonsillitis, adenitis, otitis media and cellulitis. Their chief habitat is the human upper air passages and thence through a variety of agencies—fingers, instruments and possibly air—puerperal infection is derived. The risk of infection with the most dangerous strains can be largely removed by elimination from the environment of all persons with inflammatory conditions of the upper air passages caused by or favoring multiplication of hemolytic streptococci. The application of this knowledge may be considered from two points of view: (1) in the absence of puerperal pyrexia; (2) on the occurrence of puerperal pyrexia.

1. In the absence of puerperal pyrexia, swabbing of the midwife in attendance should not be done, unless she shows signs of an acute or chronic inflammatory condition of the tonsils, pharynx, nose or middle ear. Every midwife should be instructed to report any symptom of such a condition at once, whereupon she should be suspended from duty and swabs should be taken for bacteriologic examination. In the event of obtaining a positive swab there may be some doubt whether the hemolytic streptococci found are responsible for the clinical condition or are merely temporary invaders. The distinction is important, as they are more dangerous when they are responsible; but there is no known bacteriologic method of making this distinction: the number of colonies is no criterion of the presence or absence of an infective process. Therefore every midwife who has reported nasopharyngeal symptoms and has been found to be a carrier of hemolytic streptococci should be suspended. If the streptococci belong to group A she must not resume duty until she has recovered completely and three negative swabs at

daily intervals have been obtained. Pupil midwives should be examined and those who have a chronic infection of the tonsils or sinuses with hemolytic streptococci should be advised that it is likely to prevent them from practicing midwifery.

2. On the occurrence of puerperal pyrexia, steps should be at once taken to ascertain its cause and until genital infection with hemolytic streptococci has been excluded the attendants must not conduct a labor or nurse any other puerperal woman. It has been shown that whenever there is a streptococcal infection of the body of the uterus the organisms will be present in the vagina. If the infection is limited to the vagina or perineum (it very rarely is) nothing is to be gained, but the contrary, by passing a swab into the cervix. Therefore a vaginal swab should be taken in every case of puerperal pyrexia unless the physician can be sure that the fever is not due to infection of the genital tract. This involves examination of a large number of swabs, many of which will not yield hemolytic streptococci. Nevertheless bacteriologic examination of a vaginal swab can rarely be omitted with safety. If it yields hemolytic streptococci, an attempt should be made to ascertain whether any of the attendants are a possible source of infection. Swabs should be taken from the nose and throat and from any cutaneous lesion of the physician or midwife. But, if streptococcal infection of the patient is suspected from the outset, swabs from the attendants should be sent for examination at the same time as the vaginal swab. If any attendants are found to harbor hemolytic streptococci they must cease to attend labors or to nurse other puerperal women until three negative swabs, taken at daily intervals from both the nose and the throat, have been obtained and clinical signs, if any, have disappeared.

PARIS

Prophylaxis Against Bubonic Plague

Samoilowitz, during an epidemic in Russia in 1778, observed that those who had been stricken but survived seemed immunized. He sought, like Jenner, to inoculate the pus of buboes containing an attenuated virus. Similar inoculations were safely made in other cases. In 1891 Yersin was able to isolate the bacillus. By repeated punctures he obtained a culture stock which immunized nine tenths of the rats on experimentation. He even inoculated himself, but the epidemic which he had observed in Hong Kong terminated spontaneously. It was Strong in Manila who in 1906 first practiced systematic preventive inoculation. At present the plague is endemic in several countries, notably Madagascar, where from 3,000 to 4,000 cases occur annually.

Yves Gérard in a recent paper described the conditions under which he combated plague in Madagascar. His vaccine was prepared chiefly from an E. V. stock cultured by monthly transplantations since 1926. Thereby an attenuation of the virus was brought about. The injections induced perfect immunization in animals about the tenth day, lasting for nine months. In man the vaccination was performed by the injection of 0.2 cc. of a culture emulsion after a forty-eight hour refrigeration. It induced splenic reactions which indicated immunization. At first, lepers in the advanced stage of the disease and volunteer physicians and male nurses were inoculated, without the least accident, and then the inhabitants of endangered villages. The original doses were increased without any grave incidents. In the district of Emyrne 46,879 natives were thus vaccinated; 60,000 served as controls. In the first group, mortality from plague was 0.47 per thousand and the general mortality 4.8. In the control group mortality was 1.66 per thousand and the general mortality 9.7, twice greater. During the three years 1935-1937, 791,160 inhabitants of the high plateaus were inoculated. Mortality was reduced

from 3,493 in 1933-1934 to 596 in 1937-1938, an 80 per cent reduction. Mortality could probably be reduced still more, he said, by intensifying vaccine concentrations. In Java, where Kolle's bacterial vaccine was used, mortality was reduced only 50 per cent. Apparently the E. V. Madagascar stock is superior to the Tsiwidej Java stock for purposes of inoculation.

Osteopathies Due to Vitamin C Deficiency

According to Policard and Leriche, bone regeneration in fractures begins with a decalcification stage, followed by calcium precipitation essential to calcium formation. These calcium localizations are related perhaps in a causal way to a circulatory activity at the bone level. However, causal relationship cannot be asserted. Microscopic observations, for example, show an extreme tissue congestion at points level with the epiphyses or metaphyses during the decalcified phase, but it cannot be determined whether this congestion is active or passive. On the other hand, in secondary lime precipitations observed in the periphery of the bone, or in the para-osseous mesodermal tissues, the periosteal tissues are the seat of hemorrhagic edemas that indicate circulatory slowing and stagnation apparently favorable to the secondary process of peripheral recalcification.

G. Mouriquand and V. Edel, in the course of investigations made especially by means of x-ray examinations, the results of which they reported to the Academy of Medicine, sought to determine to what extent calcium metabolism was modified under acute, subacute or chronic conditions of vitamin C deficiency. They observed that about the fifteenth day the epiphysal and metaphysal areas first become decalcified and then softened. In acute or subacute cases this reabsorption of calcium was not accompanied with any change, no calcium being carried to the periphery. In chronic states, on the contrary, induced by the addition of 0.5 mg. of ascorbic acid (either synthetic or lemon juice) hypertrophic and often osteophytic calcium deposits were observed about the seventieth day and in all cases before the one hundred and twentieth day, accompanied with ankylosis of the posterior portion.

Mouriquand and Edel think that a certain lapse of time is necessary for the transfer of calcium from the central bone regions to the periphery. Whether the calcium reabsorbed during the time preceding the transfer remains in the bone tissue in a transitional state or is eliminated by the feces or urine, making room for other extra-osseous calcium supplies, raises questions more easily asked than answered, though observed experimentally and radiographically. Since vitamin C deficiency, like vitamin D deficiency, is a factor in decalcification, the regimen in bone fractures must be adjusted to prevent it.

BERLIN

(From Our Regular Correspondent)

Jan. 3, 1940.

Further War Measures

The premature granting of medical appointments because of the dearth of physicians in the absence of the state medical examination does not *ipso facto* confer the degree of doctor of medicine, even if an acceptable dissertation has been submitted. It is ordered that doctoral examinations be postponed until the required medical education has been completed and the required training service has been made up. The salary of these students of medicine, prematurely and exceptionally approved and assigned to sick fund service, is to be placed on a footing fundamentally equal with that of physicians previously appointed. It is therefore permissible to appoint them at once as assistants in hospitals where vacancies exist.

The identification tag that every soldier in the German army must wear around his neck will henceforth indicate the blood group to which he belongs.

In accordance with regulations requiring economy in filling out prescriptions containing fats, alcohols and similar sub-

stances of value for war purposes, fats of all kinds may now be prescribed only under the most stringent need. Soap may be prescribed only in quantities indispensably necessary to promote recovery. The prescription of medicines rich in sugar, such as cough syrups, should be carefully checked. The cultivation of medicinal plants in the vegetable gardens of the hospitals of Berlin has continually been increased. In 1938, 4,440 square meters of land was planted with camomile, 4,015 with peppermint, 1,540 with sage, 7,984 with valerian, 2,300 with primrose, 500 with lilies of the valley. Iodine and its derivatives may be sold in drug stores only on medical prescription.

Vitamin Needs of the Navy

Two navy physicians, Drs. Stutz and Weispfennig, report in *Der deutsche Militärarzt* investigations on the vitamin needs of sailors made at the Baltic Sea marine station. They were unable generally to confirm the observations made by others that 50 mg. of ascorbic acid is insufficient for daily needs under conditions existing on board ship. This amount of vitamin C is sufficient for conditions on land when physical exertion is moderate. The authors found that a combination of vitamin C and B₁ was superior to the sole use of vitamin C. The most favorable results were obtained by the use of lemons. A distinct superiority of natural vitamins over artificial products was noted. Environmental factors, such as sun irradiation, play an important part in vitamin metabolism. They recommend provisionally a combined use of vitamin C and B₁ for men at sea. The utilization of high grade lemon extract is, according to the authors, very limited on board ship. Germany does not import such large quantities of lemons as would be required nor would there be room enough on board ship for the barrels of lemon extract needed. The authors recommend a haw marmelade to be made at 176 F. with oxygen control and to be consumed on bread.

Control of Rickets

The minister of the interior has directed all governmental health bureaus to summon all mothers of infants from 3 to 12 months of age for a medical examination in connection with measures designed to combat rickets. If signs of rickets are noted, the mother receives a bottle of irradiated ergosterol with instructions to add five drops daily to the food. The bottle contains a supply for about two months. The child is then reexamined and additional medicine given. If after a third examination symptoms of rickets are still present, the child is assigned to the supervision of a physician. If the mother is unable to pay for the service, social security provisions and, if necessary, the public welfare program of the national socialist party guarantee the expense. No parents are exempt from the regulations requiring infant examination. These measures represent a new kind of prophylaxis on a large scale, similar to that governing the vaccination of a populace. It is estimated that about 1,500,000 infants will be subject to the first examination. These general tests will enable the government also to determine the actual spread of rickets. Heretofore the local statistics available have been so conflicting that no general conclusions could be drawn from them.

Increased Consumption of Alcohol in Germany

According to the most recent statistics the production of beer, which increased in the fiscal year of 1937-1938 9.3 per cent (3.7 million hectoliters) showed a still greater increase in the fiscal year of 1938-1939, namely 10.3 per cent (4.51 million hectoliters). The total of 48.11 million hectoliters represents an increase of about 43 per cent over the low totals for 1932-1933. Simultaneously the consumption of alcohol increased to a still greater degree. In the first quarter of the year 1939-1940 there was noted a still further enhancement of beer consumption in Germany.

BELGIUM

Jan. 4, 1940.

Use of the Radioscope in the Army

Toussaint discussed the systematic use of radioscopy of the lung in freshly mobilized recruits before the Belgian society of radiologists. Since roentgenography could not be considered for economic reasons, radioscopy might prove immensely serviceable in detecting pulmonary tuberculosis, at present amounting to 1 per cent of the fighting forces. Otherwise lesions would tend to spread and increase under the strain of exercise and fatigue and increase the drain on the national treasury. The systematic use of the radioscope required: 1. Medical personnel consisting of four radioscopists chosen after their eyesight had been tested. They would not be radiologists but internists specially trained for examinations of this kind. 2. Proper equipment consisting of a movable x-ray apparatus, suitably protected. In order to avoid delays, adequately lighted gangways would facilitate the passing of the men behind the screen. 3. A smoothly functioning organization that did not interfere with military activities. Under the conditions mentioned, about 100 men could be examined in one hour.

Diphtheria Control in the Schools

Perkowsky, speaking before the Belgian association of social medicine, pointed out that diphtheria cases were still numerous. The speaker discussed the procedures in use to prevent diphtheria, such as the closing of schools, inoculation, detection of germ carriers and isolation of those infected. These measures, he said, have proved insufficient. The detection of germ carriers took too much time and in epidemics the results of the examination of specimens ran the risk of being too late to permit an effective prophylaxis. While declaring himself in favor of inoculations thoroughly and extensively performed, Perkowsky proposed regular daily examinations in school centers in time of epidemics. These examinations, conducted by school physicians, required no complex organization and permitted serum injections at once, on the least suspicion. Serum injections, promptly administered and in sufficient quantities, he said, were efficacious in all cases.

Hospitalization of Indigent Tuberculous Patients

In the report of the minister of public health, figures are given indicating the ravages of tuberculosis since the World War. The increase before and after the war can be noted from the following comparison: If 100 is taken to represent the number of deaths per hundred thousand in 1913, the mortality in 1918 for the different countries was 109 for France, 144 for England, 164 for the Netherlands, 154 for Germany and 208 for Belgium. Although good reasons exist for believing that Belgium will not again suffer a debilitation period like that of 1914-1918, the public health department is considering a plan that aims at the isolation of tuberculous patients in sanatoriums. At present these institutions receive three kinds of patients: those who pay for their services, social insurance beneficiaries and the indigent. Numerous communes, however, do not have the resources to care for indigent patients in a sanatorium. The health department plans to meet the needs of the third class. Provincial communal funds have been created entrusted with the hospitalization of tuberculous and carcinomatous persons. To extend their activities, that is to double the number of those hospitalized, it is estimated that 16,000,000 francs will be needed annually.

Diseases of Workers in Cotton Factories

Before the Belgian association of social medicine, Thiry set forth the results of an inquiry begun last year in which about 310 workers in cotton mills were examined. His attention in this inquiry was directed: 1. To the considerable incidence,

at every age level, of enlarged lymph glands, chiefly in the neck and axillae. 2. To the extremely numerous cases in young persons of abnormal modification of the blood pressure. Hypotension was exceptional, hypertension common and at times high. In certain cases hypertension could be attributed to pulmonary sclerosis, which affects numerous cotton mill workers. However, hypertension could not thus be accounted for in youthful workers presenting no pulmonary lesions that might affect the circulation. 3. To modification in the sedimentation rate.

International Union Against Venereal Diseases

The "Union internationale contre le pèril vénérien," founded by Professor Bayet in 1922, held its annual meeting in Liège, June 24-28, 1939. The following resolutions and recommendations were passed and copies sent to all governments which have representatives in the union: 1. Antivenereal dispensaries should make available to their patients the new resources of antigonococcus chemotherapy in conjunction with the gynecologic services rendered to women affected with gonorrhea. 2. Sulfanilamides intended for the internal chemotherapeutic treatment of gonorrhea should be delivered only on a nonrenewable medical prescription. The union went on record requesting that the governments make arrangements with the military authorities that no special measures, such as penalties and prolongations of the time of service, be resorted to when soldiers were known to have venereal disease, since such measures resulted in withdrawing a great number of infected from medical examinations and treatments.

Trends in Cardiology

According to Dautrebande, who discussed the present tendencies and evolution of cardiology before the Belgian cardiologists (Journées Belges de Cardiologie), cardiology is more and more taking its orientation from physiology. Too much importance, attached for a long time to clinical symptoms, kept the cardiologists from studying the problems of cardiac function. At the source of this function is found the cardiac output. This permits early diagnosis of heart failure long before clinical studies have been made. However, of greater interest to cardiologists than the heart is the periphery of the heart. The speaker pointed out the significance of tests that estimate the strength of oxygen administration. The problem consisted here in maintaining the tissues and especially the myocardium under conditions of normal oxygenation. He demonstrated the value of oxygen for the circulation by showing its effects in hypertension produced by renal ischemia.

Marriages

JOHN STAIGE DAVIS JR., New York, to Miss Florence Roome at East Williston, N. Y., Dec. 9, 1939.

LAMBERTUS E. BEEUWES to Miss Hilda G. Smith, both of Dearborn, Mich., in December 1939.

IVAN WILLARD BROWN JR., Newfane, N. Y., to Miss Madeline Davis at New York, Dec. 28, 1939.

JOHN S. BEASLEY, Centerville, Tenn., to Miss Allie Brown Regeon at Franklin, Dec. 14, 1939.

BURNETT B. FORMAN, Indianapolis, to Miss Margaret Nelson, of Union, Wash., Sept. 14, 1939.

JEFF N. WEBB, Seneca, S. C., to Miss Willie Sue Boleman, of Townville, Dec. 29, 1939.

ANDREW MUNTAN, Detroit, to Miss Mary Chargo at Bowling Green, Ky., February 1.

CLARENCE B. SACHER to Miss Rose Mary Hargrave, both of Dallas, Texas, Dec. 1, 1939.

ELWYN S. SHONYO, Elgin, Ill., to Miss La Von Abraham, of Chicago, January 13.

GEORGE REXNER JR., Cincinnati, to Miss Naomi Butler in January.

Deaths

Harry Milton Weed @ Buffalo; University of Buffalo School of Medicine, 1903; professor of ophthalmology emeritus at his alma mater; member of the American Academy of Ophthalmology and Otolaryngology; fellow of the American College of Surgeons; ophthalmologist to the Buffalo General, Millard Fillmore, Children's, St. Mary's Maternity, Erie County, and Buffalo City hospitals, Buffalo, and Moses Taylor Hospital, Lackawanna; served during the World War; aged 65; died, Dec. 5, 1939, of coronary occlusion.

John Grant Quimby, Lakeport, N. H.; Medical School of Maine, Portland, 1888; at various times member of the house of representatives and state senate; for many years member of the board of education and chairman of the board of health; chairman of the board of trustees of the Laconia (N. H.) State School; aged 77; died, Dec. 12, 1939, of cerebral hemorrhage.

Frederick Henry Thompson, Fitchburg, Mass.; Harvard Medical School, Boston, 1870; member of the Massachusetts Medical Society; member of the House of Delegates of the American Medical Association in 1911-1912; for many years on the staff of the Burbank Hospital; aged 95; died, Dec. 14, 1939, of arteriosclerosis.

William McIlwain, Detroit; University Medical College of Kansas City, Mo., 1898; in 1929 was awarded the Distinguished Service Cross by the War Department for gallantry in action while serving with the "Lost Battalion" during the World War in France; aged 81; died, Nov. 28, 1939, of cerebral arteriosclerosis.

Oscar Emanuel Grant @ Chicago; College of Physicians and Surgeons of Chicago, School of Medicine of the University of Illinois, 1905; fellow of the American College of Surgeons; on the staff of the Swedish Covenant Hospital; aged 60; died, January 4, at Fairhope, Ala., of heart disease.

Thomas A. Moore, Plainview, Texas; Memphis (Tenn.) Hospital Medical College, 1900; at one time health officer of Briscoe County; formerly on the staff of the Wichita Falls (Texas) State Hospital; aged 64; died, Dec. 29, 1939, of chronic myocarditis.

Ortus Fuller Adams, Trinidad, Colo.; Northwestern University Medical School, Chicago, 1901; veteran of the Spanish-American and World wars; formerly county coroner; aged 62; died, January 3, in Mount San Rafael Hospital of hypertension and uremia.

Burton J. Simpson, Chicago; Rush Medical College, Chicago, 1900; member of the Illinois State Medical Society; on the staff of the Englewood Hospital; aged 69; died, January 8, of Parkinson's disease, cerebral arteriosclerosis and pneumonia.

Stewart Slocum @ Fortville, Ind.; Central College of Physicians and Surgeons, Indianapolis, 1900; past president of the Hancock County Medical Society; aged 71; died, Dec. 18, 1939, at Van Nuys, Calif., of injuries received in an automobile accident.

Pierce A. Meck, Nanticoke, Pa.; Jefferson Medical College of Philadelphia, 1884; member of the Medical Society of the State of Pennsylvania; formerly president of the board of health and health officer; aged 80; died, Dec. 4, 1939, of senility.

George Augustus Cherry @ Flushing, N. Y.; University of the City of New York Medical Department, 1891; formerly on the staffs of the New York Foundling and Bellevue hospitals, New York; aged 69; died, January 17, of heart disease.

Frank Albert Foster, Los Angeles; University of Michigan Department of Medicine and Surgery, Ann Arbor, 1885; at one time coroner and health officer in Charlevoix County, Mich.; aged 81; died, Dec. 23, 1939, of coronary thrombosis.

Peter F. Sheaffer, Christiana, Pa.; Jefferson Medical College of Philadelphia, 1881; member of the Medical Society of the State of Pennsylvania; aged 80; died, Nov. 29, 1939, in the Lancaster (Pa.) General Hospital of uremia.

Herbert William Plummer, Lime Spring, Iowa; Kcokuk (Iowa) Medical College, College of Physicians and Surgeons, 1905; member of the Iowa State Medical Society; aged 62; died, Dec. 5, 1939, of sarcoma of the lungs.

Frank Reynolds Fleming, Philadelphia; Hahnemann Medical College and Hospital of Philadelphia, 1911; on the staff of the Belmont Hospital; aged 52; died, Dec. 12, 1939, of cerebral hemorrhage and arteriosclerosis.

George Alanson Crittendon, Springfield, Mass.; Dartmouth Medical School, Hanover, N. H., 1908; aged 59; died, Dec. 5, 1939, in the Springfield Hospital of cerebral hemorrhage, arteriosclerosis and chronic nephritis.

Norman Irving Broadwater @ Oakland, Md.; University of Maryland School of Medicine, Baltimore, 1909; bank president; aged 57; died, January 3, in the Memorial Hospital at Cumberland of cerebral hemorrhage.

David Merring Milholland, Defiance, Ohio; Miami Medical College, Cincinnati, 1884; member of the Ohio State Medical Association; aged 81; died, Dec. 26, 1939, in a hospital at Toledo of arteriosclerosis.

James McIntire Fleming, Blairs Mills, Pa.; Medico-Chirurgical College of Philadelphia, 1896; aged 70; died, Nov. 8, 1939, in the Lewistown (Pa.) Hospital of cirrhosis of the liver and arteriosclerosis.

Francis B. Warnock, Sioux City, Iowa; State University of Iowa College of Medicine, Iowa City, 1882; member of the Iowa State Medical Society; aged 80; died, Dec. 28, 1939, of coronary thrombosis.

Raymond Evan Bailey, Hamlin, W. Va.; Medical College of Virginia, Richmond, 1927; member of the West Virginia State Medical Association; aged 37; died, January 7, in a hospital at Huntington.

Argolis O. Varner, Union Star, Mo.; Missouri Medical College, St. Louis, 1882; for many years bank president; aged 87; died in December 1939 in St. Joseph of cerebral hemorrhage and arteriosclerosis.

James Nathan Rohrbach, Palm, Pa.; Jefferson Medical College of Philadelphia, 1904; aged 68; died, Dec. 19, 1939, in the Sacred Heart Hospital, Allentown, of pneumonia and paralysis agitans.

William Cowley, Pittsburgh; Hahnemann Medical College and Hospital of Philadelphia, 1886; aged 75; died, Dec. 20, 1939, in Sherman, Conn., of chronic myocarditis, hypertension and thrombosis.

William Franklin Strangways, Little Rock, Ark.; M.B., Trinity Medical College, Toronto, Ont., Canada, in 1876 and M.D. in 1878; aged 83; died, Dec. 30, 1939, of carcinoma of the prostate.

C. Colfax Smith, Clarksville, Iowa; Northwestern University Medical School, Chicago, 1904; member of the Iowa State Medical Society; aged 71; died, Dec. 5, 1939, of coronary sclerosis.

Luella Z. Rummel, Kansas City, Mo.; Hering Medical College, Chicago, 1901; Eclectic Medical University, Kansas City, Mo., 1917; aged 75; died, Dec. 27, 1939, of mitral stenosis.

Willoughby H. Reed, Jeffersonville, Pa.; Jefferson Medical College of Philadelphia, 1882; formerly a druggist; aged 83; died, Dec. 19, 1939, in Deland, Fla., of heart disease.

Fred Lee Johnson, Detroit; Cleveland Homeopathic Medical College, 1903; served during the World War; aged 61; died, January 7, of a self-inflicted bullet wound.

Thomas Jefferson Williams, Bogalusa, La. (licensed in Louisiana in 1925); aged 67; died, Dec. 17, 1939, in New Orleans of acute dilatation of the heart.

Maurice Freiman, New York; University and Bellevue Hospital Medical College, New York, 1908; aged 55; died, Dec. 22, 1939, of cerebral hemorrhage.

Harold Attig Miller, San Francisco; Jefferson Medical College of Philadelphia, 1914; aged 49; died, Nov. 11, 1939, of coronary thrombosis and myocarditis.

Hilmar Munster, Belmont, Calif.; University of Rochester (N.Y.) School of Medicine, 1929; aged 35; was found dead, Dec. 21, 1939, in a hotel at Berkeley.

Luther W. Bowman, McAllen, Texas; State University of Iowa College of Medicine, Iowa City, 1886; aged 80; died, Dec. 29, 1939, of myelogenous leukemia.

Weden M. Tibbitts, Topeka, Kan. (licensed in Kansas in 1901); aged 75; died, Dec. 30, 1939, of hypertension, chronic myocarditis and diabetes mellitus.

Richard S. Starkey, Seattle; Jefferson Medical College of Philadelphia, 1895; aged 73; died in December 1939 of heart disease and gallbladder infection.

John Patterson Hartwell, Elmira, N. Y.; Long Island College Hospital, Brooklyn, 1886; aged 78; died, Dec. 3, 1939, of cerebral hemorrhage.

H. Dudley Young, Los Angeles; Harvard Medical School, Boston, 1895; aged 72; died, Nov. 22, 1939, of prostatism.

Correspondence

PELLAGRA

To the Editor:—I read with keen interest your recent article on pellagra and note that you have given a lot of credit to Goldberger. Have you read the paper by George H. Searcy on "An Epidemic of Acute Pellagra" (*Tr. M. A. State of Alabama*, 1907, p. 387)? His paper is quite enlightening because of its priority. He discussed the symptoms, diagnosis, pathology, prognosis and treatment. He made the statement that "the essential management consists in placing the patient in good hygienic surroundings and trying to improve the general health by good nourishing food and such tonics as may seem indicated" (p. 390). In the discussion that follows the paper Dr. Searcy states that "it might be well for the profession to look out for these diseases, especially among Negroes, who often times have nothing more to eat than corn bread and a little meat." His remarks concerning the nurses' diets and those of the patients are interesting and might have given Goldberger an idea as to his research.

Dr. Searcy died a few years ago; I am writing because of my own interest in seeing that priority is given to his work.

EMMETT B. CARMICHAEL, PH.D., University, Ala.

"BURN SHOCK"

To the Editor:—In their article "Burn Shock," published in the Dec. 16, 1939, issue of *THE JOURNAL*, Trusler, Egbert and Williams state that they frequently observed low blood sugar values in dogs in which various degrees of burns had been produced experimentally. They further state that they are unable to explain these low values but feel that this point should be considered in the treatment of burn shock.

In an article entitled "Pathogenesis of Death from Burns" (Greenwald, H. M., and Eliasberg, Helene: *Am. J. M. Sc.* 171:682 [May] 1926) we reported two cases in which children aged 2 and 3 years respectively died of burns. One child was observed to have an entire absence of sugar in the blood and the other child had 30 mg. per hundred cubic centimeters. This was striking in view of the fact that Underhill had just described a series of cases in which an increased concentration of sugar in the blood had been found.

Our observations led us to believe that perhaps there were other factors than just the physicochemical changes of shock responsible for the changes in the blood sugar content. We therefore studied, experimentally, blood sugar levels in burns and the effect of burns on the organs most concerned in the regulation of blood sugar levels, using the rabbit as the experimental animal. We observed that a marked rise in blood sugar values occurred uniformly in all the rabbits within a few hours after the burn; the greatest rise occurred in the rabbits that were most severely burned and that presented the greatest degree of shock. In seven rabbits a marked drop followed the initial rise.

All except one rabbit showed a marked decrease in either muscle or liver glycogen or both. Microscopic examination of the pancreases showed normal glandular structure; the liver, aside from the absence of or a decrease in glycogen, showed no striking changes. The adrenals, however, showed definite changes. In the animals that died within three or four hours after the burn increased cellular activity was found; in those that lived for from twenty-four to forty-eight hours definite degenerative changes were found but were associated practically always with evidence of regeneration.

Since in the initial stage of a severe burn marked hyperactivity of the adrenals was found, we concluded that this was responsible to a great degree for the high blood sugar values noted. The glycogen content of the livers as well as of the

muscles was markedly decreased in these rabbits. These facts tended to bear out the assumption that an outpouring of epinephrine into the circulation occurred as a result of the increased secretory function of the adrenal glands. In the later stage the destructive changes in the adrenals were responsible for a decreased amount of epinephrine thrown into the blood stream and thus inhibited the liver in its normal glycogenolytic function, with resulting hypoglycemia.

If one can apply conclusions drawn from experimental burns in animals to burns in man, it can be stated that in the first stage of a severe burn the high blood sugar level observed is due not to blood concentration alone but also to increased adrenal secretion and that the low blood sugar observed at a later stage is in part due to failure of the adrenals.

H. M. GREENWALD, M.D., Brooklyn.

SENSITIVITY TO SOLUTION OF POSTERIOR PITUITARY

To the Editor:—Occasionally during the past few months I have seen communications in *THE JOURNAL* referring to hypersensitivity to solution of posterior pituitary. This reminds me that in November 1931 I had a case of allergic reaction from the injection of solution of posterior pituitary following the third stage of labor. Apparently the patient almost died and was saved only by the prompt administration of epinephrine.

I reported this case to the manufacturer (Parke, Davis & Co.) and was advised by the chief of the research department (Dr. Kamm) that this was the first instance of which he had ever heard of allergic reaction from solution of posterior pituitary. Later, with the assistance of the American Medical Association library and Dr. Kamm, I reviewed the literature and found four or five cases reported from abroad. I then prepared a brief paper on the subject of hypersensitivity to solution of posterior pituitary and submitted it to *THE JOURNAL* for publication. It was returned with a notation that, while it was an unusual report, it did not seem to be an occurrence of sufficient interest to warrant publication. It is a source of some satisfaction to me to learn that my observation in 1931 of hypersensitivity to this preparation is now being confirmed by other observers.

J. STREET BREWER, M.D., Roseboro, N. C.

LIPOID PNEUMONIA

To the Editor:—The editorial "Lipoid Pneumonia" (*THE JOURNAL*, January 20) is timely and forceful, but it falls far short of its potential value by reason of two serious omissions.

Reference to Drs. P. R. Cannon and T. E. Walsh should recall at once "The Problem of Intranasal Medication," published in the *Annals of Otolaryngology and Rhinology* in September 1938. In this report was proof that the so-called mild silver proteins argyrol and neosilvol provoke pulmonary tissue reaction with consequent damage to lung tissue similar to that produced by liquid petrolatum. These products are still in common, although diminishing, use by the profession and public alike.

Also, having pointed to the wrong road, had you indicated the right one you would have added utility to enlightenment. Thus, the same investigators demonstrated that isotonic saline solutions of ephedrine and related vasoconstrictors caused no reaction in pulmonary tissue. This coincides with previous studies on their relation to nasal and sinusal epithelium. The investigators, therefore, advocate these solutions as the medications of choice for local nasal treatment.

The modern trend is toward a physiologic approach to rhinologic problems. This is a sound but revolutionary change in a specialty that has lagged behind all others in clinging to empiricism. The evidence produced by Laughlen, and more recently

Queries and Minor Notes

THE ANSWERS HERE PUBLISHED HAVE BEEN PREPARED BY COMPETENT AUTHORITIES. THEY DO NOT, HOWEVER, REPRESENT THE OPINIONS OF ANY OFFICIAL BODIES UNLESS SPECIFICALLY STATED IN THE REPLY. ANONYMOUS COMMUNICATIONS AND QUERIES ON POSTAL CARDS WILL NOT BE NOTICED. EVERY LETTER MUST CONTAIN THE WRITER'S NAME AND ADDRESS, BUT THESE WILL BE OMITTED ON REQUEST.

by Walsh and Cannon, shows clearly the dangers of empiricism. For a generation nostrums of little use and much harm have been prescribed and widely used. Not only has the practice been unscientific and harmful, it has evidenced a notable lack of curiosity in a speciality in which ingenuity has been notably abundant.

My feeling is that failure to make correction will not be missed by the manufacturers of the "mild silver" nostrums whose advertising is always with us.

S. N. PARKINSON, M.D., Oakland, Calif.

GERIATRICS AND DIET

To the Editor:—In the article by Dr. E. I. Tuohy in THE JOURNAL January 20 entitled "Geriatrics in Relation to an Adequate Energy Producing and Protective Diet," there are two points that call for comment. These two corrections, one major and one minor, in no way detract from the general excellence of the article, which stresses matters in the diet of older persons for which the physician may unwittingly have been at fault, limiting more and more of the diet until there is less and less of the patient to eat it.

In referring to the word geriatrics, Dr. Tuohy says that "Masters introduced it in a thesis in 1914. . . ." Dr. I. L. Nascher was the author of a large textbook, "Geriatrics," published in 1914, at which time the name came into some general usage. However, in a letter received from Dr. Nascher in July 1938 there is the following (with the permission of Dr. F. R. Packard): "The name was not coined in 1914 but in a paper published in the *New York State Medical Journal*, Aug. 21, 1909. I gave a talk on geriatrics before the New York County Medical Society in 1910 and 1911; lectured on geriatrics at Bennett Medical College, Chicago, now Loyola University School of Medicine, in 1911 and 1912, and at Fordham Medical College, 1913-1914." For the sake of accuracy and to settle the point of priority, this excerpt of Dr. Nascher's letter should be sufficient.

The second point has to do with a quotation from my paper entitled "History of Geriatrics (*Ann. M. Hist.* 10:324 [July] 1938). The point is minor, but because the meaning has been changed slightly I should like to correct it. Speaking of the attitude toward older persons in the early stages of civilization, the correct quotation is "Religion gave them an aura, wisdom gave them a shield, and respect for accumulated surpluses extended their influence over possible heirs."

JOSEPH T. FREEMAN, M.D., Philadelphia.

LIVER DAMAGE FROM ARSENICAL REMEDIES

To the Editor:—In THE JOURNAL Dec. 30, 1939, page 2422, appears an editorial entitled "Public Interest in Venereal Disease," which states that "the number of doses of the arsenical drugs used for the treatment of syphilis amounted in the last fiscal year to 10,656,253, an increase of 84 per cent over the number of doses of such drugs used in 1933."

A cursory examination of these data along with the rules recommended by the U. S. Public Health Service reveals that they are highly commendable, but there is nevertheless a very definite warning which should be incorporated in this advice. At present our knowledge of liver function is adequate to establish the fact that one cannot use arsenic indiscriminately in all cases without occasionally producing liver damage which might subsequently cause serious consequences. In spite of the limited value of the various methods for testing liver function, liver damage due to arsenic can often be detected before clinical signs are apparent and the plan of therapy altered accordingly.

EDWIN J. GRACE, M.D., Brooklyn.

EARLY TABES: MARRIAGE, TREATMENT, PROGNOSIS

To the Editor:—A white man aged 33 acquired syphilis some nineteen years ago in Egypt. He was intensively treated with arsenicals and with preparations of bismuth and mercury for a period of eleven years. No definite data are available as to the number of treatments or the dosage the patient received. Following a rest period of about sixteen months he was again treated for a period of four years, this time in England. For the next two years he received no treatment. He never had the spinal fluid examined, while the Wassermann reaction always remained four plus. Within the past year and a half he has received fourteen injections of neoparsamine 0.6 Gm., sixty injections (six courses) of bismuth salicylate of tryparsamide 0.3 Gm. The blood Wassermann reaction at the beginning of the treatment was four plus and at the end of it three plus. The spinal fluid examination showed the Wassermann reaction 2 plus, the Kahn reaction 2 plus, a mild syphilitic colloidal gold curve (122321000), the first globulin 3 plus (moderate trace), cell count 20 cells per cubic centimeter. At the end of the last series of treatments the spinal fluid Wassermann reaction was 1 plus, the Kahn reaction 2 plus, a weak syphilitic colloidal gold curve (1123221000), this result being negative from another laboratory, globulin 3 plus and the cell count 8 cells per cubic centimeter. The patient's general physical examination is essentially negative except for absent knee jerks. There are no cardiovascular signs or symptoms and no abnormal mental signs. The right pupil is smaller than the left, but both react to light and in accommodation. The Romberg sign is negative. The problem this patient presents concerns my advice to him about marriage as well as his mismanaged treatment in the past and the proper treatment in the future. Both the patient and his fiancée are aware of the nature of his condition as well as the probable hazard at economic liability. The questions which must be answered are: 1. Is marriage advisable? 2. What are the chances of his wife being infected? 3. What are the possibilities of their children having congenital syphilis? 4. What would the ordinary progress of his disease be under supervision and treatment and without it? 5. Could he carry on a normal life should his disease appear checked? Is life expectancy shortened? 6. What should his future treatment consist of, how long, and what is the prognosis?

M.D., New York.

ANSWER.—Before replying to the specific questions it is necessary to discuss the diagnosis and treatment of the case in question. While the data given as to neurologic examination are inadequate, nevertheless the inequality of the pupils and the absence of the knee jerks suggest that the patient has early tabes dorsalis. This suggestion is strengthened by the fact that the spinal fluid is abnormal. However, it is quite impossible to interpret the two spinal fluid examinations. The statement given that the Wassermann and Kahn tests on the spinal fluid are 1+ or 2+ has no significance in permitting any determination of the degree of spinal fluid abnormality or in correlation of serologic with clinical observations. The only permissible conclusion is that the patient's spinal fluid contains some reagin. Spinal fluid examination is hopelessly incomplete unless it includes a quantitatively titrated complement fixation test (Wassermann test), using varying amounts of fluid ranging from 0.1 cc. to a maximum of 1 cc. If the complement fixation test is positive with the smallest amount of fluid named, 0.1 cc., the quantitative titration should be carried even lower, as for example, 0.05 cc., 0.025 cc., and so on. It is perhaps not absolutely necessary to have these data in order to plan intelligently for the immediate future, but the spinal fluid examination should be carried out in the manner indicated in the future, in order to determine progress and the desirability of termination of treatment.

As to past treatment, it can be said that sixteen and a half years of continuous chemotherapy is ridiculous for any type of syphilitic infection and is clearly indicative that the treatment given, while perhaps more than satisfactory in amount, has been less than satisfactory in type. It is taken for granted that when the inquirer mentions a dose of tryparsamide as 0.3 Gm. he actually means 3 Gm., since the former dose is homeopathic.

Nothing can be said as to the results of the treatment so far given from the serologic point of view. A change in the blood Wassermann reaction from 4+ to 3+ is of no significance. The change in the blood test, like that in the spinal fluid, cannot be estimated unless the test is quantitatively titrated.

To proceed now to the specific questions:

1. There is no medical reason to object to this patient's marriage provided his fiancée is aware of the nature of the condition and the probable hazards of economic disability, as the inquirer states that she is.
2. The chance of the patient's wife becoming infected is infinitesimally small and can be almost completely ignored. For

all practical purposes, syphilis is not infectious to the wife after the infection in the marital partner has existed for five years or longer.

3. There is no possibility that any children will have congenital syphilis unless the wife is infected. Congenital syphilis is never transmitted by the father alone and occurs only after the father infects the mother.

4. It is quite impossible to offer any estimate as to the progress of this patient's disease without further treatment. There is some chance that he might go happily through life without the development of any further symptoms or physical signs, even though additional treatment is not given. However, since he has already shown definite evidence of organic damage of the nervous system and since spinal fluid abnormalities still persist, it might be guessed that there is approximately a 50 per cent chance or greater of further progress if additional treatment is not given. If, on the other hand, the patient is properly treated from this point on there is approximately a 95 per cent certainty of complete arrest of the process at its present level.

5. He can carry on a normal life should his disease appear checked. Life expectancy is probably not shortened.

6. Since sixteen and a half years of chemotherapy has been unsuccessful in preventing the development of neurologic abnormalities clinically and in the spinal fluid, it may be taken for granted that further treatment of this sort is likely to be without avail. The patient should be immediately treated with non-specific fever therapy, preferably with malaria, during the course of which he should be allowed to have from ten to twelve paroxysms, in each of which temperatures of 104 F. or over should be attained. Following the completion of the malaria treatment he should undergo six months of further chemotherapy with trypanamide, twenty-six consecutive injections of 3 Gm. each, the first and last eight of which are combined with simultaneous intramuscular injections of bismuth subsalicylate suspension in oil, each 0.2 Gm. At the completion of this amount of treatment, and regardless of the serologic status, treatment may be at least temporarily discontinued. Following the completion of treatment the patient should be kept under observation indefinitely. For the first three years the blood and spinal fluid should be retested every six months, the blood test being carried out by a quantitative technic, the spinal fluid examination also including a complement fixation test by the quantitative technic described. At yearly intervals the patient should undergo a complete physical examination, with particular emphasis on the cardiovascular and central nervous systems. After three years of this sort of probation the periodic examinations of blood and spinal fluid and physical examinations may be done at yearly intervals instead of six months. They should be continued, however, at intervals of a year for an indefinite period, certainly from five to eight years, and thereafter at least as often as every two years. Treatment need not be resumed unless there is evidence of clinical progress or serologic relapse on a quantitative basis. It is entirely probable that the blood test will remain positive indefinitely and somewhat less likely, though quite possible, that abnormalities may persist in the spinal fluid Wassermann test. The cell count, protein and colloidal tests are likely to become negative. The persistence of these serologic abnormalities, unless they grow distinctly worse on the quantitative basis, however, is not an indication for the resumption or continuation of treatment.

CIRCUMCISION IN WOMEN

To the Editor:—Every once in a while I hear an outburst from an osteopath in this neighborhood on circumcision in women. Kindly give me any information as to the ethics and value of this sort of procedure, if any.

M. F. Smith, M.D., Roton, New Mexico.

ANSWER.—Circumcision in women is not often required, except for hygiene; accumulated smegma beneath an adherent prepuce sometimes is the cause of persistent annoying inflammation. There appears to be little foundation for the belief that an adherent clitoris is often responsible for frigidity; circumcision seldom increases libido. In this connection it may be pertinent to emphasize that the distance from the urethral meatus to the clitoris, accepted to be 2 cm. in the average case, is sometimes 3 cm. or more, and tends, particularly, to approach the latter figure in women who are frigid. The question arises as to whether the increased distance of the clitoris from the vaginal canal may account for some cases of unsatisfactory reaction at intercourse.

In those infrequent cases in which an adherent prepuce causes annoyance, freeing of the prepuce from the clitoris accompanied by a simple dorsal slit ordinarily accomplishes all that can be achieved with a more elaborate circumcision. Circumcision of women certainly cannot be recommended except in rare instances.

LATENT SYPHILIS

To the Editor:—I have had under constant treatment a man aged 40, on American, since Oct. 4, 1938. When first seen he had extensive ulcers of the right lower leg of four months' duration which had failed to heal and had been diagnosed as varicose ulcers. The patient's Wassermann, Eagle and Kline reactions were all four plus. He has been faithful in his treatment, having received forty injections of maphorsen 0.06 Gm., and has also received 2 cc. of bismuth salicylate in oil, forty injections. The ulcers on his leg healed promptly and have remained healed. He is clinically free from symptoms but continues to show a four plus Wassermann reaction. The spinal fluid Nov. 4, 1938, showed a negative Eagle reaction. Wassermann and Kline tests were not made. The colloidal gold curve was 0000110000 and a second spinal puncture was made October 21 which showed the Wassermann reaction negative, Hinton reaction negative and Pandy test for globulin negative but colloidal gold 222110000. (The patient has also received a large amount of iodide.) What further treatment, if any, should he receive? What should he be told as regards further treatment and the presence or absence of central nervous system syphilis?

M.D., California.

ANSWER.—Apparently this patient falls in the group of so-called "Wassermann fastness," which is a poor term for a persistently positive Wassermann reaction in an individual who has become asymptomatic. The two negative spinal fluid tests eliminate the possibility of neurosyphilis as a background for the persistently positive Wassermann reaction, and if careful examination of the cardiovascular system is negative for aortitis it then seems justifiable to classify the case as one of latent syphilis with a persistently positive Wassermann reaction.

The treatment to date has been good and it seems advisable from now on to limit it solely to the use of bismuth compounds, preferably two courses with twelve injections to the course each year for the next two years. After that it seems advisable to place the patient on parole and have him return for physical examination each year.

Although a history of acute syphilis is lacking in the inquiry, it is probable that the patient has had his syphilis for ten or more years. If this is true, further treatment than the two years of bismuth compounds is not necessary. If in addition to the two negative spinal fluid examinations he shows no clinical signs of neurosyphilis, the patient may be told he does not have central nervous system syphilis.

POSTTRAUMATIC PSYCHOSES

To the Editor:—I would appreciate some information as to present opinions concerning the acute psychotic episodes which sometimes occur as post-operative or posttraumatic complications: 1. In what proportion of these cases is alcoholism a factor? 2. In known alcoholic addicts who come in for acute surgical procedures, is it advisable to give them alcohol in the postoperative period as a preventive measure? 3. Is alcohol advisable therapeutically? 4. Is there any value in insulin provided the patient is not diabetic? 5. What drugs are most satisfactory for quieting the patient and in what doses? 6. What is the general duration of this complication? 7. What is the approximate mortality? 8. Please outline the procedure to adopt in treating a case.

Henry S. Huber, M.D., New York.

ANSWER.—1. Alcoholism has a definite influence on the development of acute psychotic episodes following operations and trauma.

2. The sudden deprivation of alcohol after operation must be avoided.

3. Alcohol has no other therapeutic value.

4. Insulin has no value unless the patient is diabetic.

5. Morphine one-fourth grain (0.016 Gm.) or its derivatives probably serves best in control, but their administration should be used only in nonaddicts.

6. It lasts usually a few days but maybe longer.

7. There is no mortality from the psychotic episodes alone.

8. Fluids and sedatives should be used.

ABSORPTION OF AIR BY TISSUES

To the Editor:—I should like to inquire how long air will remain in a wound before being absorbed: first in a lacerated wound which is left open, second in a cutaneous wound which penetrates fascial planes but without laceration of deeper tissues, in which the cutaneous wound is closed.

M.D., Ohio.

ANSWER.—The time during which air will remain within the tissues depends almost entirely on the quantity introduced. The best evidence has been obtained in cases of tuberculosis in which measured quantities of air have been introduced into the pleural cavity in the production of artificial pneumothorax. It is estimated that 500 cc. of air introduced into a normal pleural cavity is absorbed within two weeks. The amount of air that might ordinarily be introduced into a penetrating or lacerated wound would be entirely absorbed in a few hours.

RECURRENCE OF PLACENTA PRAEVIA

To the Editor:—A patient had a normal pregnancy and delivery in 1933 and placenta praevia in 1934 and again in 1936. She desires more children but hesitates because of past experiences. What are her prospects? Is there a predisposition to placenta praevia in certain individuals and, if so, can anything be done about it?

M. A. Kline, M.D., Dalton, Pa.

ANSWER.—Placenta praevia is not likely to recur in subsequent pregnancies. In a careful study of some 300 patients with placenta praevia, the condition recurred in only two individuals. This incidence is no greater than the incidence in pregnancy. It is therefore unlikely that the patient referred to would have a repetition of her experiences. She can be encouraged to become pregnant again.

STREPTOCOCCI IN THROAT OF CHILDREN'S NURSE

To the Editor:—In the opinion of public health authorities does the routine finding of *Streptococcus viridans* or *Streptococcus hemolyticus* in the throat of a healthy girl make it dangerous or inadvisable to employ her as a nurse for young children? I have advised the mother of the children that the organisms are frequently found on routine examination and are of no significance.

Edward F. Briggs, M.D., Mount Kisco, N. Y.

ANSWER.—*Streptococcus viridans* is found in all adult throats and is of no significance. Hemolytic streptococci in the throat of a nurse would be objectionable and a source of danger to children.

EARACHE AND MENSTRUATION

To the Editor:—In further comment on "Earache and Menstruation," which appeared in *Queries and Minor Notes* in The Journal, May 27, 1939, page 2196, I should like to mention the following additional references: Kuttner writes in his book "Die nasalen Reflexneurosen" (nasal reflex neuroses) (1904): Haug reports four women with sensations of pain and subjective sounds in the ears, which either appeared or were intensified during the menstrual period. By cocaineization or by cauterization of the nasal mucosa the pains could be overcome. The paper by Haug is titled "Ueber die Beeinflussung gewisser subjektiver Ohrenscheinungen durch Behandlung der genitalen Sphäre der Nase (modification of certain subjective ear symptoms by treatment of the genital sphere of the nose)" *Monatsschrift für Ohrenheilkunde*, 1903, p. 96.

Isac Bamberger, M.D., Jerusalem, Palestine.

FLUOROSCOPY IN MINIMAL TUBERCULOSIS

To the Editor:—In *Queries and Minor Notes* in The Journal, there appears an answer to the question "Will you kindly inform me as to the reliability of fluoroscopic examination in detecting cases of minimal tuberculosis?" It seems to me that this question was completely decided many years ago and decided in the negative. Fluoroscopic examination of the chest, properly performed by trained radiologists and other physicians, permits the detection of extensive pulmonary lesions, many of them not detectable by ordinary physical examination. However, fluoroscopic examination alone causes one to overlook approximately 20 per cent of "positive" cases, including cases of active pulmonary tuberculosis. (Vaigland, Wolf: *Röntgenpraxis* 7: 433 [July] 1935. Licht, Eric de Fine: *Acta radiol.* 17: 105 [April] 1936. Dunham, Kennon: *Am. J. Roentgenol.* 1925 and following volumes). The detection of minimal cases of tuberculosis requires the combination of competent roentgenographic examination, occasional fluoroscopic examination, and correlation of the results with associated clinical and laboratory data.

L. H. Gorland, M.D., San Francisco.

BODY ODOR

To the Editor:—In *Queries and Minor Notes*, Jan. 27, 1940, page 346, there is a discussion headed "Body Odor, or Bromidrosis." This almost certainly is a neurotic reaction to a normal odor. All the evidence for this conclusion is present in the inquirer's letter. His question would be better answered by a psychiatrist.

Franklin C. McLean, M.D., Chicago.

To the Editor:—In *Queries and Minor Notes* in the Jan. 27, 1940, issue of The Journal, on page 346, the answer to the inquiry regarding body odor or bromidrosis, although adequate in some respects, does not in my estimation fully cover the other possibilities presented. In the first place, the doctor presenting the question has stated that although he has seen the patient on several occasions he could note nothing more than the usual odor present around the perineum. It seems to me that the possibility of this condition being entirely subjectively present has been overlooked, and no consideration has been given in the answer to a condition, although rare, which is sometimes seen in women who have symptoms at a hippocampal gyrus or uncinate process tumor along the olfactory tract. In these cases hyperosmia or offensive odor is induced by the patient alone and cannot be substantiated, since the reception of this so-called smell is of central origin. Another condition, although the patient is rather young for it, which might have been mentioned is that of psychotic disturbances associated with the menopause.

Ludwig G. Ledcrer, M.D., Chicago.

Medical Examinations and Licensure

COMING EXAMINATIONS

STATE AND TERRITORIAL BOARDS

Examinations of state and territorial boards were published in THE JOURNAL, February 17, page 605.

NATIONAL BOARD OF MEDICAL EXAMINERS

NATIONAL BOARD OF MEDICAL EXAMINERS: Part II, May 1-2; Part III, June or July, to be given in medical centers having five or more candidates desiring to take the examination. Exec. Sec., Mr. Everett S. Elwood, 225 S. 15th St., Philadelphia.

SPECIAL BOARDS

AMERICAN BOARD OF ANESTHESIOLOGY: An Affiliate of the American Board of Surgery. Oral. Part II. New York, June 10-11. Applications must be received 60 days prior to examination. Sec., Dr. Paul M. Wood, 745 Fifth Ave., New York.

AMERICAN BOARD OF DERMATOLOGY AND SYPHILOLOGY: November 1940. If a sufficient number of applications are received before March 1 there will be an examination at New York, June 10-14. Sec., Dr. C. Guy Lane, 416 Marlboro St., Boston.

AMERICAN BOARD OF OBSTETRICS AND GYNECOLOGY: General oral and pathologic examinations (Part II) for all candidates (Groups A and B) will be conducted in Atlantic City, N. J., June 7-10. Applications for admission to Group A, Part II, examinations must be an file not later than March 15. Sec., Dr. Paul Titus, 1015 Highland Bldg., Pittsburgh (6).

AMERICAN BOARD OF OPHTHALMOLOGY: Oral. New York, June 8-10; Cleveland, Oct. 5. Sec., Dr. John Green, 6830 Waterman Ave., St. Louis.

AMERICAN BOARD OF OTOLARYNGOLOGY: New York, June 3-5. Sec., Dr. W. P. Wherry, 1500 Medical Arts Bldg., Omaha.

AMERICAN BOARD OF PATHOLOGY: New York, June 10-11. Sec., Dr. F. W. Hartman, Henry Ford Hospital, Detroit.

AMERICAN BOARD OF PEDIATRICS: Memphis, Tenn., Nov. 17, preceding the annual meeting of the American Academy of Pediatrics. Sec., Dr. C. A. Aldrich, 723 Elm St., Winnetka, Ill.

AMERICAN BOARD OF PSYCHIATRY AND NEUROLOGY: Cincinnati, May 17-18. Sec., Dr. Walter Freeman, 1028 Connecticut Ave. N.W., Washington, D. C.

AMERICAN BOARD OF RADIOLOGY: New York, June 7-10. Sec., Dr. Byrl R. Kirklin, 102-110 Second Ave., Rochester, Minn.

AMERICAN BOARD OF SURGERY: Various centers, April 1. Sec., Dr. J. Stewart Rodman, 225 South Fifteenth St., Philadelphia.

California August Examination

Dr. Charles B. Pinkham, secretary, California State Board of Medical Examiners, reports the written examination held at Los Angeles, Aug. 8-10, 1939. The examination covered nine subjects and included ninety questions. An average of 75 per cent was required to pass. Seventy-seven candidates were examined, seventy of whom passed and seven failed. The following schools were represented:

Book Notices

Modern Clinical Psychiatry. By Arthur P. Noyes, M.D., Superintendent, Norristown State Hospital, Norristown, Pennsylvania. Second edition. Cloth. Price, \$5. Pp. 570. Philadelphia & London: W. B. Saunders Company, 1938.

The author who wishes to write a useful book on psychiatry is confronted with the problem of how much to include. Encyclopedic textbooks of psychiatry similar to those which are so readily available in internal medicine and surgery seem as yet to have no place in the library of the psychiatric student. Since the subjects covered by the conventional textbooks of mental medicine are more or less the same, the value of such books must rest on their modernness, the fluency of their presentation and the interest engendered thereby, as well as the accuracy of the facts presented. The first edition of Noyes's textbook stood out. It had all the characteristics which are indispensable for satisfactory textbooks, and the selection of matter as well as the style were better than those in most of the other psychiatric works. The present edition has been somewhat improved. Some of the contents have been brought down to date, in fact, so much so that the chapter on schizophrenia closes with several excellent pages dealing with shock treatment of that disorder, a development largely of the past two years. In spite of the fact that nonhospital psychiatrists, of whom there are now a large number, have to deal with conditions other than the psychoses, the majority of chapters of Noyes's book deal only with those major mental disorders which usually require hospitalization. Only the last three chapters are of any value to the general medical man or to the psychiatrist who has to deal with conditions which might be seen in an outpatient department of a hospital or in the private office. There is no chapter on child guidance. There is little on criminology except what is included under psychopathic personality. The presentation of hospital cases, of the frank psychoses and of that material which forms the groundwork of psychiatry, however, is satisfactory and this book ranks well up with the other textbooks recommended for students of the subject written in the field of psychiatry.

The Larval Trematoda Found in Certain South African Mollusca with Special Reference to Schistosomiasis (Bilharziasis). By Anne Porter, D.Sc., F.R.S.S., F.L.S., Research Associate in Zoology, McGill University, Montreal. Publications of the South African Institute for Medical Research No. XLII (Vol. VIII). Paper. Pp. 492, with 2 illustrations and 83 plates. Johannesburg, 1938.

Schistosomiasis is a widespread disease of man, other mammals and birds. It is due to infection by adult flukes which live in the blood stream and whose abundant eggs lodge in the capillaries of the bladder and intestine, producing local inflammation and not infrequently resulting in neoplasms. The eggs, discharged in urine or feces, hatch in water into free-swimming miracidia, which bore into fresh-water snails, pass through larval stages and emerge as fork-tailed free-swimming cercariae, which pierce the skin of the vertebrate host and find the blood stream, in which they complete the complicated life cycle.

All public health measures in prophylaxis and local eradication of the disease rest on the zoologic knowledge of the habits, life history, ecology and immunology of both the parasite and its intermediate host or hosts, for the fluke adapts itself to various mollusks.

This debilitating and potentially dangerous infection of man depends for its continuance on insanitary habits of infected persons whose urine and feces continuously containing fluke eggs are deposited in or otherwise find their way into bodies of water in which the snail hosts feed and breed. These same waters are usually the sources of water for drinking, and also the public laundry and bathing resort of young and old. Thus the vicious circle is maintained.

The biologic intricacies of the blood fluke problem appear in the following facts: There are two prevalent types of the disease, the urinary and the intestinal, due to two different flukes, *Schistosoma haematobium* and *S. mansoni*, living as larvae in different snails. The two diseases, the two flukes and the varied molluscan hosts are spread over the whole of watered inhabited South Africa as well as widely over the tropics, and a third fluke, *S. japonicum*, is repeatedly brought in by Orientals in shipping and travel. Further complications arise from the facts that the snail hosts have also other fluke infections and that other snails

BOOK NOTICES

683

may be susceptible to the infection. Man is liable also to be attacked by the skin-penetrating cercariae of the flukes parasitic in other mammals which give rise to swimmers' rash. It is virtually impossible to exclude snails from public water supplies and natural waters used for bathing. Copper sulfate in the ratio of 1 to 500,000 or even 1,000,000 is effective in killing most of the snails.

The author's recommendations based on biologic evidence include prevention of contamination of public waters by human feces and urine, protection of the individual from infection, and destruction of the molluscan hosts and of the infective cercariae. The first can be accomplished by sanitation in modern cities but is difficult with illiterate and uninstructed native peoples with established modes of life and no sanitary conveniences. The second means providing cercariae-free water from deep wells for bathing consists of allowing the snail-free water to stand seventy-two hours before use, since the larvae die within that time after leaving the snail. The treatment and cure of all infected persons will also accomplish the same end locally and for a time. The last can be carried out largely by engineering control of all artificial waters in which periods of drought can be utilized to kill off the snails and reduce the water to areas available for treatment with copper sulfate. The disease in man yields to continued use of antimony and potassium tartrate.

This book is a mine of information on fluke infections of snails. The text and illustrations record and picture no less than 112 different cercariae from twenty-eight species of South African mollusks. There are also fully illustrated accounts of the morphology, larval stages, intermediate hosts and ecology of the schistosome flukes of man and his domestic animals. Experimental work on modes of infection, behavior and immunologic reactions is included. The book is a superb piece of parasitologic work in one of the most important fields of human parasitology carried out with a broad vision of the most essential biologic principles involved, with a wealth of detail and a high degree of accuracy.

Sport, Physical Training and Womanhood. By Stephan K. Westmann, M.D., L.R.C.S., L.R.C.P. With a foreword by Sir Kaye Le Fleming, M.A., M.D., Member and Vice-Chairman, Medical Sub-Committee, National Fitness Council, England. Cloth, Price, \$4. Pp. 222, with 73 illustrations. Baltimore: William Wood & Company, 1939.

This astonishing volume, written by a physician who appears to have been trained in Germany, impels the reader to turn to the title page to discover whether its date is 1889 but he finds it printed as 1939. Further, he discovers that the author is set down as eminent both as an obstetrician and as an athlete. But his astonishment is abated no whit, for the author's principal thesis is that girls and women should not engage in competitive sports lest their child bearing be made impossible or difficult. "The champion of today, in all probability, has already suffered injuries that will bring her tomorrow to a doctor's consulting room . . . with health shattered." "Many competitive sports necessitate sexual abstinence for men while training."

"Too much activity in sports of a masculine character causes the female body to become more like that of a man. This holds good . . . in regard to the genital organs, for they tend to a swiftly moving tennis ball, striking her abdomen, because injury to the organs of the lower part of the abdomen. Few persons who have played tennis regularly for forty years have ever been struck in the abdomen by a swiftly moving tennis ball and it would do nothing but make the skin smart if they were. The ball is a light one.

When discussing riding, the author ventures the thought that the side saddle tends to a somewhat strained posture. As a good sport for women he suggests lacrosse, one of the most dangerous and violent games played by our young men. One shudders at the thought of a lacrosse stick striking a woman in the abdomen.

The author's entire trend of thought is foreign to the line of progress in the United States during the last fifty years, although it may be more acceptable for Germany. He is quite right in stating that competitive exercise may be overdone by women—or men. His general presentation of the effects of competitive exercise on women is quite unconvincing to an American.

On one page he attempts to demonstrate that physical activity reduces the size and changes the shape of the pelvis so as to make child bearing difficult. On another page he recalls to our minds that only civilized and modern women have such difficulties and that childbirth among primitive women was a simple and relatively easy physiologic function. In the name of all that is true and beautiful, what were the physical activity habits of those primitive women? They may not have ridden side saddle but they have been charged with being continuously active. Some good exercises for use during pregnancy and the puerperium are given in the latter part of the book, but there are so many inaccuracies, inconsistencies and anachronisms that the reader must lose confidence in the good material also.

Cancer of the Larynx. By Chevalier Jackson, M.D., Sc.D., LL.D., Consultant in Broncho-Esophagology Research, Temple University Medical School, Philadelphia, and Chevalier L. Jackson, A.B., M.D., M.Sc., Professor of Broncho-Esophagology, Temple University Medical School. Cloth. Price, \$8. Pp. 309, with 239 illustrations. Philadelphia & London: W. B. Saunders Company, 1939.

The authors in the preface explain the division of the book into three parts under the headings of procedures, general considerations and historical notes as being an attempt to furnish information from three different points of view. In the first instance their aim is to present briefly such practical information as may be applicable to a particular case in hand. The second division provides a broader basis for study, for comparison of results by methods and for expanding the reader's knowledge through a discussion of pathology, diagnosis, borderline cases and subjects that are still of a controversial nature. The third part of the book is designed to round out the picture by detailing the historical development of our knowledge of this fascinating subject. Needless to say, the authors have done a good job. Stripped of nonessentials, the consensus of our present day knowledge of cancer of the larynx is presented in orderly fashion so that he who runs may read and profit. In addition to Jackson's subperichondrial laryngofissure, which the authors have long favored and with which they have had remarkable success, they present the details of both "narrow field" and "wide field" laryngotomy as well as the modifications which have been in vogue from time to time. The chapter on articulate speech after laryngectomy, though brief, furnishes considerable information in this perplexing subject, and the chapter on treatment of cancer of the larynx by irradiation is marked by a sane and cautious consideration of what is still a moot question. As might be expected, Jackson's colored drawings of the laryngeal picture under various states of disease are present in sufficient number to delight the eye and stimulate the observer to more careful observation and appreciation of the images he sees in his mirror. This excellent little book successfully bridges the gap since Thompson's publication in 1930 and brings the laryngologist's library down to date in a vital and absorbing topic.

The Measurement of Adult Intelligence. By David Wechsler, Chief Psychologist, Bellevue Psychiatric Hospital, New York. Cloth. Price, \$3.50. Pp. 229, with 12 illustrations. Baltimore: Williams & Wilkins Company, 1939.

The author points out that for some time there has been a distinct need for good tests of adult intelligence. The modified Binet test contains a poor means of differentiation between the smart and the dull adult, although the dull adult, of course, can be compared with a child. With the help of some Works Progress Administration workers and his own staff, Wechsler at the Bellevue Psychopathic Hospital in New York has developed a new scale which is especially adapted for the evaluation of adult intelligence. In discussing some of the factors involved in measuring adult intelligence the author goes on to explain some of the details which were elicited by developing the present scale. For instance, one of the things that are noticeable is that test results in an adult scale decrease with age. There are other factors which apparently have never been adequately studied on adults, which Wechsler has studied. While many of the tests on this scale are modified from the older Binet scale and the performance scales in general use in clinics and mental hospitals, he has added some which are specific to the present method of measuring. One of these is a good general knowledge test. Various facts of the scale have been adequately validated according to methods which are commonly used. The author shows a few special statistical methods in a part of the

book devoted to the subject. The test apparently is quite reliable. Wechsler devotes considerable time to a discussion of the selection and description of the test, the population used in standardizing the test, the results of standardization, and the limits and special merits of the scale. He also has tables which are used in the easy determination of the intelligence quotients. All in all, the author presents a new technic which should be of some value to psychiatrists who have bemoaned the lack of the means of evaluating that trait which is so necessary of evaluation but so little understood—general adult intelligence. The present test certainly is a step forward, providing the psychologist working with the psychiatrist another tool in the diagnosis of mental patients.

Protozoology. By Richard Roksabro Kudo, D.Sc., Associate Professor of Zoology, the University of Illinois, Urbana. Second edition of Handbook of Protozoology. Cloth. Price, \$6.50. Pp. 689, with 291 illustrations. Springfield, Illinois, & Baltimore: Charles C. Thomas, 1939.

This new edition of the author's Handbook of Protozoology (1931) has been completely rewritten, reset and greatly enlarged. Whereas the first edition had 175 illustrations showing 1,463 figures, this edition has 291 illustrations with 2,711 figures. As now constituted it offers the content of textbook, laboratory manual, reference work and an atlas of the free-living and parasitic Protozoa. The first six chapters treat of the ecology, morphology, physiology, reproduction and variation and heredity of the Protozoa, and chapters 7 to 43 give a systematic analysis of the families, many of the genera, and the more significant and representative species of this marvelously diverse group of so-called simple organisms. It is a valuable work of reference for every medical library.

Practical Obstetrics. By P. Brooke Bland, M.D., Consulting Obstetrician, Jefferson Medical College Hospital, Philadelphia, Pa., and Thaddeus L. N. Thompson, M.D., Clinical Professor of Obstetrics, Jefferson Medical College, Philadelphia, Pa. Third edition. Cloth. Price, \$8. Pp. 877, with 1,000 illustrations. Philadelphia: F. A. Davis Company, 1939.

A critical review of the previous edition of this book was published in THE JOURNAL Feb. 2, 1935. In rewriting and revising the book for the present edition, the authors gave consideration to some of the points mentioned in the previous review. In this revision, particular attention has been given to the chapters on toxemias of pregnancy, endocrine physiology, obstetric anesthesia and the treatment of the newborn. This edition contains 502 engravings, including twenty-seven colored plates, whereas the second edition contained twenty-one colored plates. The illustrations in general are good. As the book is intended primarily for students, the authors have kept in mind brevity and directness. That the text has been brought abreast of the time is shown in the chapter on the treatment of puerperal complications by means of sulfanilamide, which the authors say is of value in septic puerperal complications when infection is due to the streptococcus; however, its effect and action should be closely watched, in view of the untoward reactions that occur in some cases. The final chapter, entitled "Obstetric Jurisprudence," precedes the section on referred reading, which gives the references that were consulted in the preparation of the book. This edition contains a few more pages than the second edition, but it remains a handy and good-looking volume.

Microbiology and Pathology. By Charles F. Carter, B.S., M.D., Director, Carter's Clinical Laboratory, Dallas, Texas. Second edition. Cloth. Price, \$3.25. Pp. 735, with 190 illustrations. St. Louis: C. V. Mosby Company, 1939.

This textbook, written primarily for student nurses, is largely devoted to bacteriology. Considerable space is devoted to general principles and methods, which are described in simple form. The portion discussing pathology for schools of nursing of high standards is somewhat deficient in text on the general phases. The chapters on special pathology include descriptions of laboratory observations, which in most books are usually segregated under clinical pathology. Illustrations are numerous and include twenty-five good colored plates. Each chapter ends with a list of helpful questions for review. A glossary of common medical terms is a useful addition. It is difficult to evaluate books for nurses, as the courses in bacteriology and pathology vary considerably; but, on the whole, this volume will meet the requirements of most training schools.

A Textbook of Pathology for Nurses. By Coleman B. Rabin, B.S., M.D., Associate in Medicine and Assistant Radiologist to the Mount Sinai Hospital, New York. Second edition. Cloth. Price, \$1.75. Pp. 266, with 68 illustrations. Philadelphia & London: W. B. Saunders Company, 1939.

The material is presented by the author in an elementary manner so that the fundamentals of pathology can be readily grasped by nurses. There is a departure from the usual style of compiling textbooks on pathology, as the author endeavors to stress the pathologic physiology of diseases in which nursing has an important part. The chapters on ulcers, obstruction of the gastrointestinal tract and obstruction of the urinary tract demonstrate this point. In spite of these features the treatment of the material is somewhat inadequate. Diseases of the central nervous system, the blood and the blood forming organs are barely mentioned. The chapter on clinical pathology is similarly short and inadequate. However, the numerous illustrations and diagrams add considerably to the value of the contents.

Bureau of Legal Medicine and Legislation

MEDICOLEGAL ABSTRACTS

Malpractice: Alleged Negligence in Treatment After Conization of the Cervix.—The plaintiff suffered from a retroverted uterus, an eroded and encysted cervix, appendicitis and dysmenorrhea. The defendants performed an operation on her Feb. 17, 1934, consisting of the removal by electrosurgery of a conical-shaped portion of the lower end of the cervix, in the region of the external os, after which the cervix was packed with iodoform gauze. An abdominal operation was then performed for the suspension of the uterus and the removal of the appendix. Alleging that subsequent disabilities experienced by the plaintiff were due to the negligence of the defendants in performing the conization operation, the plaintiff brought suit and obtained a judgment for \$7,500, from which the physicians appealed to the Supreme Court of Iowa.

From the record, said the Supreme Court, it was evident that in an operation of the kind performed on the plaintiff raw surfaces are left around the cervical canal, and if nothing is done to prevent them coming in contact they will occlude and close the canal. The evidence showed that the only thing done to keep the canal open was to place gauze in it, which was removed a day or two after the operation. From the date of the operation until the time that the plaintiff left the hospital nineteen days later, the jury could have found from the evidence, the court said, that, with the exception of the removal of the gauze, there was no examination of the cervix, no treatment of the wound and nothing done to hold apart the raw surfaces. The following April, May and June the plaintiff had periods of intense suffering, and on June 24 she applied to the defendants for relief. At that time the cervical canal was opened with dilators, no anesthetic being given. The plaintiff was in the hospital about twenty-four hours at that time. Again in July and in August she suffered cramps with great intensity and severity in length of time. She again appealed to the defendants for aid on August 11 and at that time the cervix was "grown over with the same sort of scar tissue as before." Again the cervical canal was opened with a dilator, without the use of an anesthetic, but no precaution was taken to prevent future occlusion. November 25, the plaintiff returned to the defendants for treatment, but she refused to go to the hospital for the purpose of again having the cervical canal opened up, stating that she could not stand the pain. She apparently returned home without any treatment. Early in December 1934 another practitioner attempted to establish an opening in the cervical canal but was not successful and thereafter removed the uterus.

The defendants complained that the trial court erred in submitting to the jury, as a basis for finding the defendants liable, the subsequent treatment following the plaintiff's discharge from the hospital in 1934. But, the court said, the petition did not limit the treatment to the time the plaintiff was in the hospital.

She employed the defendants to treat her, until she had recovered. The defendants knew that the operation necessitated a long subsequent period of treatment in order to effect a cure. The site of the operation required inspection, to see whether the wound was healing properly; it required "dressing," and this was the duty and responsibility of the defendants.

A medical witness testified that the procedure and methods used by the defendants were not those ordinarily used; that it was essential for the canal to be kept open and for keeping the canal open various methods were used, and that inspection had to be made frequently to see that the canal was kept open. While there was some conflict in the testimony on the part of the other physicians who testified on behalf of the defendants, the question was one for the jury. The defendants further argued that the trial court erred in failing to instruct the jury properly relative to the plaintiff's burden of showing the necessity of removing the uterus. It was the defendants' theory that the jury, in determining the matter of necessity, should consider only opinions of experts regardless of whether or not the experts themselves had fixed any standard of necessity. One physician, said the court, might say that what was necessary was to be gaged by whether the plaintiff's life depended on a certain course. Another might think that necessity should be gaged by whether the plaintiff's intense discomfort or pain could be avoided by the removal of the uterus. Still another physician might think that preservation of the ability to bear children was more important than the risk of death or long suffering and therefore that the plaintiff should be subjected to a risk of death or long suffering rather than have the uterus removed. For this reason, the court pointed out, the opinion of physicians as to the fact of necessity is not controlling on the jury. The jury is well able to say whether the preservation of life, the freedom from long pain or suffering or the preservation of the power to bear children, regardless of the risks that might accompany it, shall be the standard of necessity.

The defendants finally objected to the testimony of a physician who lived in a community some 70 miles from the one in which the operation was performed, on the ground that the witness was not qualified to testify. But, said the court, the undisputed evidence showed that the witness was qualified in all respects regarding his knowledge of this particular type of operation and his testimony showed the standard of practice of the general locality surrounding the city of operation. To lay down a rule, the court said, that no one could testify except a physician from the particular town in which the medical man being sued lived would be unfair and unreasonable. A physician is bound to exercise that skill and care ordinarily possessed under like circumstances, not merely in the same community but in like localities.

The court could find no error in the record, and the judgment for the plaintiff was affirmed.—*Kirchner v. Dorsey & Dorsey (Iowa)*, 284 N. W. 171.

Medical Practice Act: Charter of State Naturopathic Association Inadmissible as Evidence.—One C. L. Hawkins was convicted of practicing medicine without a license and appealed to the court of criminal appeals of Texas.

The medical practice act of Texas provides that any person shall be regarded as practicing medicine within the meaning of the act:

1. Who shall publicly profess to be a physician or surgeon and shall treat or offer to treat any disease or disorder, mental or physical, or any physical deformity or injury, by any system or method, or to effect cures thereof.

2. Who shall treat or offer to treat any disease or disorder, mental or physical, or any physical deformity or injury, by any system or method, or to effect cures thereof and charge therefor, directly or indirectly, money or other compensation.

It was not necessary, said the court, for the information to charge that Hawkins publicly professed to be a physician and surgeon and offered to treat any disease or injury, mental or physical; it was sufficient for it to charge that he treated or offered to treat as set forth in the second quoted subparagraph. The information might have charged in the language of either or both subparagraphs, because if Hawkins did the things mentioned in either he came within the statutory definition of what constitutes the practice of medicine. Furthermore, the information did not have to negative the exceptions contained in the

medical practice act; if Hawkins came within any of the exceptions he could offer that fact as a defense.

The evidence showed that Hawkins had a sign in his yard which read as follows:

Dr. C. L. Hawkins, Telephone Number 87-3646, Chiropractor, Naturopathic, Toxine Elimination, Exercise and Health Diet and Health Service.

A person suffering from pulmonary and intestinal tuberculosis applied to Hawkins for treatment and on two different occasions Hawkins supplied the person with medicine, advising him to take a spoonful each morning and night. For this treatment the person paid \$4 on one occasion and \$3 and some cents on another. In the opinion of the court, this evidence was sufficient to sustain the conviction.

Hawkins complained because the trial court declined to permit him to offer in evidence the Charter of the Texas State Naturopathic Association. The appellate court was unable to understand on what theory this document might have been admissible. A charter granted to an association by the Secretary of State, the court said, would not authorize any one to engage in the practice of medicine without having complied with the medical practice act; nor could it relieve any one from prosecution for a violation of that act.

Finding no reversible error in the record, the court of criminal appeals affirmed the judgment of conviction.—*Hawkins v. State (Texas)*, 125 S. W. (2d) 580.

CENTRAL SOCIETY FOR CLINICAL RESEARCH

Twelfth Annual Meeting, Held in Chicago, Nov. 3 and 4, 1939

(Concluded from page 614)

Treatment of Climacteric Symptoms with Stilbestrol

DR. ELMER L. SEVRINGHAUS, Madison, Wis.: Continuing the comparison of different estrogenic substances for the relief of menopausal symptoms, it has been found possible to get complete relief in each case tested by the oral administration of the synthetic estrogen stilbestrol. A group of seventeen women have been observed over a total of seventy-five months of treatment, with the average duration of therapy four and one-half months. The individual patients received the medication for from two to eight months each. A wide range of doses has been tried, from minimum levels of 0.1 mg. a day to a maximum of 15.0 mg. a day. In only three cases was the dose of 5.0 mg. exceeded, and in only two was more than

5.0 mg. needed to continue the relief. With only one patient has there been relief from use of less than 0.5 mg. a day. The effective dose range seems therefore to be from 0.5 to 5.0 mg. daily.

Test of the adequacy of treatment by the vaginal smear shows stilbestrol to be very potent. Doses ranging from 0.5 to 5.0 mg. maintained the presence of cornified cells in a state of maturity comparable to that of the normal midinterval smears in the period of fertility. The stimulation of endometrial activity was more marked than has been the common experience with naturally occurring estrogens, as shown by the occurrence of postmenopausal bleeding in at least four of the seventeen women. In two of these the bleeding has been so bothersome that treatment was discontinued for a period.

Significant complications which have necessitated discontinuance of medication include only nausea, headache and lassitude. These symptoms have been relieved by reducing the dosage, without sacrificing clinical control. In three cases exception to this statement must be made because of the gradual development of persistent headache in one, of nausea in another and of marked lassitude in the third. These "toxic" manifestations appeared only after months of satisfactory use of the drug in 0.8, 1.0 and 5.0 mg. doses. Relief from the symptoms was secured after a number of days with no stilbestrol and return to natural estrogen therapy.

The benefits noted in this series include relief from autonomic and mental disturbances as completely as is the case with natural estrogen therapy. None of the women treated have been in a state of involuntional melancholia requiring institutional care. No objective tests for liver, kidney or bone marrow function are included in this study, but nothing about the clinical course has suggested damage to these organs. Anemia has not been a feature of the toxic manifestations. Extended studies of long time use of stilbestrol seem indicated, with tests of renal and hepatic function before and after the drug is administered.

DISCUSSION

DR. C. M. MACBRYDE, St. Louis: I can report observations which confirm in all essentials those reported by Dr. Sevringhaus. Eight months ago I started studies on diethylstilbestrol, and I have to date studied the results of treatment in thirty-seven cases of hypo-ovarianism. Each patient has been treated for at least one month, and several have been treated for eight months continuously. Of the thirty-seven patients twelve had had both ovaries removed and five part but not all of the ovarian tissue removed, five patients were of eunuchoid type with marked hypogonadism and amenorrhea, and fifteen were patients with severe symptoms of the spontaneous menopause. Diethylstilbestrol proved to be a potent estrogen when given either parenterally or orally. I have followed the vaginal smears at weekly intervals in a large number of cases and have found that estrous changes can be produced at will. The endometrium also shows definite effects as demonstrated by biopsies taken at intervals. In some instances the estrus effects can be obtained with only a few tenths of a milligram a day, and in others it takes several milligrams daily. The largest dose used was 5 mg. daily by injection. Minor toxic effects were noted in a small number of cases. I have not observed the high incidence of toxic effects which have been reported by some observers. Nausea occurred in about 20 per cent of the series and vomiting in three cases, but these symptoms ceased when the dose was reduced. To two patients the preparation has been administered in daily doses of 5 mg. by injection for six months without any signs of toxicity. The average dose employed in the series was 1 mg. by mouth or by injection daily. No cutaneous reactions were observed. No evidence of renal damage as shown by repeated urine examinations was observed. Repeated estimations of red blood cells, white blood cells, platelets and hemoglobin during and after treatment showed no variations from normal. Liver function studies have been performed in a few cases in which the largest doses were administered and treatment was given for the longest periods. So far I have failed to find any evidence of disturbed hepatic function. The tests employed were those of bromsulphalein excretion and hippuric acid synthesis. In none

of the cases has it been necessary to withdraw the preparation because of toxic manifestations. Nausea occurred after both oral and parenteral treatment but most often after injections. Changing from parenteral to oral treatment or reducing the size of the dose has so far always resulted in cessation of nausea. I have shown that subcutaneous implantation of hard pellets weighing about 100 mg. will give slow absorption with continuous mild estrous effect. The rate of absorption is about 0.1 to 0.2 mg. a day, which is equivalent to from 2,000 to 4,000 international units daily. The material seems to be more effective per milligram absorbed by pellet implantation than by injection or by mouth. These small "artificial ovaries" can be left in place for weeks or months without any untoward local reaction. They may provide a practical method for prolonged administration of small amounts of estrogenic material. If a larger dose is desired, several pellets may be implanted. I want to emphasize with Dr. Sevringhaus the possible toxic effect of this material. Animal experiments have shown that very large doses can produce liver damage and can inhibit blood formation and cause bone marrow changes. So far with therapeutic doses no such changes have been observed in patients. Nevertheless, this material should be very carefully studied before its use is widely encouraged.

DR. FRANK N. ALLAN, Boston: I can add confirmation to Dr. Sevringhaus's report with regard to the efficacy of stilbestrol. At the Lahey Clinic we have used it in forty-five cases, and I have analyzed the results in twenty-six. In twenty-four cases there was definite relief of symptoms of the menopause. In two cases treatment was discontinued because of toxic symptoms before there was time to evaluate results. In these cases treatment was begun with 1 mg. daily. In ten cases there were toxic symptoms of some degree; in all the symptoms were mild: nausea, rarely vomiting, abdominal discomfort and malaise. None of these symptoms were serious, but the fact that they have occurred so frequently must make one cautious about indiscriminate use. The material is effective when given orally, by injection and as an inunction. In two cases we have observed decided effects from inunction. Administration orally or by inunction may eliminate the need for intensive treatment by injections, sometimes required with severe menopausal symptoms.

DR. SAMUEL SOSKIN, Chicago: My experiences have been similar to those of Dr. Sevringhaus. A word about toxicity: I have found in a group of thirty cases that two or three showed mild symptoms of nausea and gastrointestinal disturbances with oral doses of 1 mg. daily. I hesitated to increase the dose above that because the dose of 1 mg. a day seemed effective in all cases, although with that dose it may take a few more days to get full relief from symptoms. I was also hesitant because of the vague rumors of toxicity passed around by word of mouth. When I started to study the effect of stilbestrol on liver function I found that in some of the treated women there was an increased retention of bromsulphalein. But when I began to study a control group of women before giving stilbestrol I found that a surprising number had some retention of bromsulphalein. It is therefore unfair to judge the toxicity of the drug by liver function tests unless one studies a sufficient number of women in the same age group before and after administering stilbestrol. I found that some patients who had mild bromsulphalein retention before had greater retention afterward, but those with no retention before treatment apparently suffered no liver damage. We may be dealing with a somewhat toxic material which will affect a damaged liver but with which a normal liver can cope very readily. I would suggest that in further evaluations the liver function be tested before one gives the material as well as after.

DR. PAUL STARR, Chicago: I have been using this material in a small way but am not yet ready to report on my observations. I should like to remind you, however, that physicians went through a horrible experience with dinitrophenol a few years ago although that drug had had the most conscientious animal, laboratory and chemical study before its clinical use. One should not be in such a rush to use a new and complicated substance for treatment of ovarian deficiency. I should

like to hear something more said about prolonged animal study on this material, particularly on the primates, if possible. The potentialities of the chemicals to be derived from this hormonal group are so great that I feel physicians are going ahead too fast.

DR. E. PERRY McCULLAGH, Cleveland: I wish to add my support to what Dr. Starr has said. It seems obvious from my clinical experience and from that of others that the toxic effects of this new drug lie very close to the effect which one wishes to obtain physiologically. Distinct experimental evidence of its toxicity has been published. Loeser discusses the damaging effects of this substance in animals in an article in the *Klinische Wochenschrift* of March 1939, and, more recently, Selye in the *Canadian Medical Association Journal* has called attention to the effects of diethylstilbestrol on the livers of rats. It is true that large quantities of the substance were used and that other estrogenic compounds are capable of producing similar damage. However, at present, when the treatment of menopausal symptoms is in a relatively satisfactory state, one should always bear in mind the potential danger of this substance. As far as possible, it would be advisable to obtain adequate information about the effects of the material on bone marrow, liver and kidneys, especially in primates, before the drug is used extensively.

DR. ELMER L. SEVRINGHAUS, Madison, Wis.: In reply to the discussion by Drs. Starr and McCullagh, I think there are some interesting situations before us. We want prolonged study of animals treated with this material and we want studies with primates as well as with rodents. That is expensive. There are not many laboratories that have monkeys to be used in this type of study and not many that are willing to spend money on trying something like this, which has large promise and one tremendous advantage over natural estrogen in that it is one-tenth as expensive. Menopausal treatment in use now is too limited; it is limited to those who can afford it, and such substances should be made available to others.

Influence of Testosterone Propionate on Function of Testes

DR. NORRIS J. HECKEL, Chicago: In persons with normal testicular function, daily intramuscular injections of testosterone propionate of 10 to 25 mg. will depress the number of spermatozoa to such an extent that either oligospermia or azospermia occurs. This depletion of spermatozoa has been observed in fifteen of seventeen patients who were treated for various urologic conditions. However, this effect was only temporary, and when the treatment was discontinued the spermatozoa counts returned to within normal limits. The longest duration of the oligospermia and azospermia was 119 days. In general, the greater the daily dose of testosterone propionate the more rapidly did sterility develop. That is, with 40 mg. daily the sterility occurred much sooner than with 10 mg.

DISCUSSION

DR. EDWARD H. RYNEARSON, Rochester, Minn.: I should like to ask Dr. Heckel if he feels that one should use testosterone propionate in the treatment of undescended testes in boys and whether he has evidence that it will cause damage to the testes of these boys.

DR. W. O. THOMPSON, Chicago: There are two important applications of these observations. It is obvious that an androgen is of no value in sterility. In the second place it should not be used for any patient who has at least one normal testis because of the danger of damaging the normal testis. For this reason it should not be used in the treatment of undescended testes unless both testes are intra-abdominal. It appears more desirable to use stimulation therapy with gonadotropic material for any person in whom the testis is capable of responding to stimulation.

DR. E. PERRY McCULLAGH, Cleveland: I wish to make one point in reply to Dr. Thompson. It has not been proved that it is impossible to produce a striking fall in the sperm count by the use of pregnancy urine extracts. This point should be investigated further. So far as is known, the effect of injection

of pregnancy urine extracts is produced only by the testis hormones secreted from the stimulated gonads. Under these circumstances it would seem to be a reasonable possibility that large amounts of a patient's own gonadal androgens might have an effect on sperm production similar to that following direct injection of similar androgenic steroids.

DR. ALLAN KENYON, Chicago: I should like to ask Dr. Heckel whether he has had the experience of finding an increased number of sperm cells in the semen of hypogonadic patients who have been treated with this material. I at one time observed a decline in the sperm count of a eunuchoid from 1 to 2 per high power field on repeated examinations to none at all, which is entirely in agreement with the report of Dr. Heckel. However, the matter is not so simple as this because there have been reports of increased numbers of sperm cells in the semen of hypogonadic patients so treated. This apparent paradox is not without parallel in biologic investigations because it has been shown that the decrease in spermatogenesis after hypophysectomy in the rat may be prevented by testosterone, and it has been reported by the Cleveland group that even after post-hypophysectomy atrophy occurs large doses of this material may revive spermatogenesis, while in the normal immature rat the seminiferous epithelium is usually inhibited. There may be varying physiologic states in patients which modify this response. I should like to have Dr. Heckel's remarks on this point.

DR. N. J. HECKEL, Chicago: I believe that too much of this material is used for urologic diseases in which at present there is not enough evidence to justify its indication; for example, benign prostatic hypertrophy, impotence and sterility. The only indication for the use of this material in the treatment of undescended testes is a condition caused by a marked deficiency of male sex hormone, in which the testes cannot be influenced by stimulating therapy (the anterior pituitary-like principle), such as eunuchoidism, genital infantilism and hypogonadism. Concerning the question of whether the number of spermatozoa in those with hypogonadism can be increased, we have observed an increase, and it is possible to see how it might occur. However, one must realize that an increase or decrease of several million spermatozoa does not mean much, because there is an error of at least 10 per cent, possibly more, in the calculation.

Use of Desoxycorticosterone Acetate in Addison's Disease

DRS. E. PERRY McCULLAGH and E. J. RYAN, Cleveland: The basis of the report is six cases of Addison's disease proved by clinical or x-ray evidence alone, by occurrence of crises or typical abnormalities in sodium and chloride excretion. Treatment with desoxycorticosterone acetate has been carried on for periods of from six to ten months. Clinical benefit has followed the use of this substance in all cases. In two cases the use of the drug together with added sodium chloride and some restriction in potassium intake has resulted in complete symptomatic control. In two cases the symptoms have been much lessened but not completely alleviated, and in two cases in which treatment was less consistent or possibly inadequate, though improvement occurred, the results were only moderately good. In conjunction with other treatment, doses as large as 10 mg. or more a day were necessary before distinct initial improvement was obvious. In all cases weight gain occurred and the blood pressure rose. Blood pressure reached levels of hypertension in five. Plasma sodium and chlorides tend to rise, while high plasma potassium tends to fall, with desoxycorticosterone administration. These values are not always consistent with the clinical condition of the patient. Desoxycorticosterone causes the negative sodium and chloride balance of Addison's disease to revert to normal, and hemocentration is corrected by it. No change in pulse, temperature, pigmentation, or dextrose tolerance has been observed as a result of this substance. Arterial hypertension and massive edema may appear as evidences of overdosage. It has been observed that patients with Addison's disease may have arterial hypertension, as a result of the use of the drug, and yet not be free from symptoms of adrenal deficiency. Under such

circumstances, adequate doses of adrenal cortex extract may relieve these symptoms and withdrawal allow their recurrence. Withdrawal of desoxycorticosterone was associated in one case with outspoken symptoms of adrenal failure, while the blood pressure was maintained at levels much above pretreatment range. Desoxycorticosterone may cause a marked shift in chloride and water retention without a parallel improvement in symptoms, and, under the same circumstances, symptomatic benefit may follow the use of adequate doses of cortical extract without a further significant change in chloride or water balance. These observations are considered to be evidence of the fact that administration of desoxycorticosterone is not complete replacement therapy. It is advised that complete dependence should not be placed in this drug to the exclusion of the use of cortical extracts in the management of Addison's disease, especially when symptoms are incompletely controlled or in the presence of crises.

Treatment of Addison's Disease with Desoxycorticosterone Acetate

DRS. W. O. THOMPSON, PHEBE K. THOMPSON, S. G. TAYLOR III and W. S. HOFFMAN, Chicago: In our experience most reports on the efficacy of desoxycorticosterone acetate are overenthusiastic. We believe this state of affairs has been caused by (1) too short periods of observation and (2) combining the administration of synthetic material with that of sodium salts so that it is difficult or impossible to determine which produced the beneficial effects. The only real test of potency of any product in Addison's disease is its ability to substitute completely for the adrenal cortex without any other form of therapy. The natural history of Addison's disease with its spontaneous remissions and relapses is too often ignored in evaluating therapeutic agents. Observations must cover a long period of time. During a period of remission, a dose of adrenal cortex extract or of desoxycorticosterone may appear to be effective even though it is inadequate to prevent the periodic appearance of crises. We have been unable to confirm Thorn's observation that 1 mg. of desoxycorticosterone acetate is equivalent to 3 cc. of Wilson's adrenal cortex extract but find that 1 mg. is equal to less than 1 cc. of extract. In severe cases of the disease, 30 mg. daily is an inadequate dose when given as the only form of therapy. There appears to be some question as to whether it will substitute completely for the adrenal cortex. Two of our patients died suddenly while receiving the synthetic material, and in two foot drop developed during the course of treatment. At least another year and probably more will be required before the status of desoxycorticosterone acetate is precisely determined.

DISCUSSION

DR. E. J. KEPLER, Rochester, Minn.: I should like to reemphasize what Dr. Thompson has said. Treatment of Addison's disease is difficult to evaluate. A number of patients do well without any medical attention. I recently saw a patient who had had Addison's disease for at least five years. She had a fondness for table salt and had acquired the habit of eating a tablespoonful of salt daily. This patient sought medical advice largely because of the increasing pigmentation of the skin. Furthermore, there are two, and often three, variables to consider in the appraisal of therapeutic measures for Addison's disease, namely the intake of electrolytes, the effectiveness of replacement therapy and finally the extent and activity of tuberculosis in the body if the adrenal insufficiency (as is often the case) is the result of adrenal tuberculosis. Therefore when dealing with such a complicated problem one should be reluctant to accept conclusions based on short term observations, especially when some patients will get along well without any systematic treatment whatever. Our experience at the Mayo Clinic with desoxycorticosterone acetate has not been altogether satisfactory. Within a comparatively short time we have had five deaths, and there is reason to believe that desoxycorticosterone acetate was implicated in these deaths. This drug did not prevent crises from occurring in two of these five cases. In one case there is considerable evidence to suggest that the fatal outcome was the result of overtreatment. There is the possibility that as yet we have not learned to

use this drug to the best advantage. In any event, I do not believe that the drug should be used except by the experimental therapist. As far as the work of Dr. McCullagh is concerned, we have sufficient unpublished data to confirm what he has said concerning the capacity of desoxycorticosterone acetate to elevate the blood pressure, to cause retention of sodium and chloride and to produce edema.

DR. SAMUEL SOSKIN, Chicago: There can be no doubt that there is a difference in the effects of desoxycorticosterone and adrenal cortex extract. I think to clear the atmosphere it might be well to ask both authors this: How many patients with Addison's disease, whether treated with cortical extract or desoxycorticosterone with salt or without salt, have been treated for a period of a year and still survive at the present time?

DR. EDWARD RYNEARSON, Rochester, Minn.: Concerning the cases of crisis mentioned by Dr. Kepler, I may add that in two of them marked anasarca developed. In one case, autopsy disclosed 1,500 cc. of fluid in each thoracic cavity, marked abdominal ascites and generalized edema. One might say that this is not the right type of case; that this drug is intended for use in milder cases. One of our patients first came to us in 1913 at the age of 15 years with acute tuberculous peritonitis. She returned in 1934 with a four months history of Addison's disease. Treatment was prescribed, using 6 cc. of cortical extract a day with the addition of salt. In 1936 she entered in crisis, from which she was rescued. In 1939 the same thing occurred. During the interval she was in good health and could continue her normal activities. Sept. 11, 1939, 368 mg. of desoxycorticosterone acetate was implanted subcutaneously. She felt well and came back on October 10 for reexamination, which showed her condition to be satisfactory. Sixteen days later sore throat developed, but her condition was not grave. The following morning she was found unconscious with a temperature of 106 F. She was given cortical extract and brought to Rochester. She arrived at 6:30 p. m. and in spite of energetic treatment she died at 4:30 the following morning. I was present some years ago when Dr. Rowntree first administered cortical hormone to a patient with Addison's disease. I am sure many of you remember how encouraged we were for we felt that this hormone might prove as effective in the treatment of Addison's disease as insulin had proved in the treatment of diabetes mellitus. We have been greatly disappointed. Our hopes were again raised when the use of this new synthetic hormone was announced. Again we are disappointed.

DR. E. PERRY McCULLAGH, Cleveland: I cannot name offhand the number of patients who have gone for more than a year with or without treatment, but it is known that patients live a long time with Addison's disease without any particular treatment at all. One patient came to me with marked leukoderma, which was found to be due to Addison's disease. The leukoderma had existed for fourteen years before treatment for Addison's disease was started. I can agree with Dr. Thompson that we still do not have the ideal treatment of Addison's disease.

DR. W. O. THOMPSON, Chicago: The first patient to whom we administered adrenal cortex extract was first treated in February 1935. When first seen she weighed 75 pounds (34 Kg.) and she now weighs 125 pounds (57 Kg.). She does all her own housework and is but little handicapped by Addison's disease. Among our patients receiving cortical extract there have been three deaths but none in the last three years. We thought it was because of inadequate treatment that death ensued. We give enormous doses in crises and much larger doses than most observers for maintenance. In contrast to these results with cortical extract, two of five patients receiving desoxycorticosterone acetate in the past six months have died.

Low Plasma Potassium and Alkalosis of a Patient with Cushing's Syndrome

DRS. D. M. WILLSON, M. H. POWER and E. J. KEPLER, Rochester, Minn.: After simultaneous administration of potassium and ammonium chloride there was a marked positive potassium balance and the electrolyte pattern of the plasma

became normal. Later the administration of potassium citrate alone was followed by an increase in potassium but also by a decrease in the bicarbonate of the plasma, whereas administration of ammonium chloride was followed by a decrease in plasma potassium and, in turn, by a decrease in chloride and a trend toward alkalosis. The response to administration of these salts and the magnitude of the potassium retention in this case suggest that the potassium metabolism was at fault, possibly as the result of hyperfunction of the adrenal cortices.

DISCUSSION

DR. E. J. KEPLER, Rochester, Minn.: I should like to comment on the use of the term "Cushing's syndrome." A few years ago Kessel made the suggestion that the clinical features that Cushing had called attention to should be called Cushing's syndrome, regardless of etiology. He further suggested that cases of Cushing's syndrome that resulted from basophilic cell tumor of the pituitary should be called Cushing's disease. We have adopted that terminology in this paper. The history of the condition Dr. Willson presented is interesting. In 1932 Cushing published a description of pituitary basophilism in *THE JOURNAL*. At that time Dr. Frank Allen, who was then associated with the Mayo Clinic, and I had under observation a patient who had the clinical features that Cushing had just described. In addition this patient had severe diabetes. As a routine procedure we determined the carbon dioxide combining power of the blood and to our surprise found it abnormally high. This patient remained under observation for a number of months and ultimately died. During the course of the disease the carbon dioxide combining power continued at a high level and at one time was as high as 110 volumes per cent. None of the factors that ordinarily give rise to alkalosis, such as vomiting, diarrhea, ingestion of alkalis or hyperventilation, were present. That was the first case of Cushing's syndrome that we saw. We looked for other cases of this type. Of some thirty cases of adrenal tumor or Cushing's disease we have encountered only three have shown any abnormality of the electrolyte pattern of the blood. As to the significance of the data presented, I am not in a position to draw unequivocal conclusions. It appears that potassium is implicated in the production of the alkalosis and that potassium ions can correct the electrolyte pattern without changing the course of the disease. Whether or not this observation implies that the adrenal cortex is hyperfunctioning I do not know, but the recent studies that were presented at this meeting on the action of desoxycorticosterone acetate suggest that such may be the case.

DR. W. S. HOFFMAN, Chicago: A few years ago I made a survey of the potassium concentration in blood serum. At that time we seldom found wide deviations of the potassium concentration from the normal level of 18 to 22 mg. per hundred cubic centimeters. A drop to a value of 12 mg. per hundred cubic centimeters occurred only once, in a patient who had just been given an injection of epinephrine. Unfortunately at that time we had no cases of Addison's disease or Cushing's syndrome to study. Serum potassium levels as low as 10 to 11 mg. per hundred cubic centimeters in Cushing's syndrome seem unusual, but we can confirm these results by showing that patients with Addison's disease who have received an adequate amount of cortical therapy and salt frequently show such low potassium levels. In fact, such patients show an electrolyte pattern similar to that reported here for Cushing's syndrome. It is difficult to evaluate this low serum potassium concentration both in cases of Cushing's syndrome or in cases of adequately treated Addison's disease. It must be significant, but I doubt whether the change in potassium concentration is primary or that it in any way accounts for the symptoms found.

DR. E. J. KEPLER, Rochester, Minn.: I did not mean to imply that the behavior of potassium was responsible in any manner for the major symptoms of Cushing's syndrome. It has nothing to do with the disturbances of the sexual characteristics. There are three essentials in the chemical picture that has been described: a low concentration of plasma potassium, a low concentration of plasma chlorides and high carbon dioxide combining power. Which of these essentials is the

primary factor is difficult to determine. The features are not exactly what one might expect to result from a hyperfunctioning adrenal cortical lesion, since low values for the plasma chlorides also occur with considerable regularity in cases of adrenal insufficiency.

Pancreatic Secretion Following Stimulation with Secretin and Acetyl-Beta-Methylcholine Chloride (Mecholyl Chloride)

MANDRED W. COMFORT, M.D., and ARNOLD E. OSTERBERG, PH.D., Rochester, Minn.: The volume of duodenal content, the hydrogen ion concentration of duodenal content and enzymatic values have been determined in work with thirteen normal persons both before and after stimulation of pancreatic secretion with secretin and acetyl-beta-methylcholine chloride (mecholyl chloride). Secretin and mecholyl chloride produced contrasting effects on pancreatic secretion. Secretin produced a large volume of pancreatic juice, increased the hydrogen ion concentration and total quantity of enzymes excreted but produced a prolonged reduction in the concentration of enzymes. Mecholyl chloride, on the other hand, increased the volume of pancreatic juice only slightly, did not appreciably affect the hydrogen ion concentration but did provoke prolonged increase in the concentration of enzymes and increased the total output of enzymes. Secretin and mecholyl chloride are satisfactory agents for the clinical study of the humeral and nervous mechanisms controlling the pancreatic secretion of man.

DISCUSSION

DR. ANDREW C. IVY, Chicago: This is obviously a good piece of work. I desire to make two suggestions for the discussion: the first is to mention what is known about the psychic secretion of pancreatic juice, and the second is to discuss the possible usefulness of secretin. When the psychic secretion of gastric juice is collected from a dog, from 30 to 60 cc. is obtained. When a human being is sham fed, from 100 to 200 cc. of gastric juice is collected. The juice collected after sham feeding is more concentrated in enzymes than the juice obtained after the injection of histamine. In the case of the pancreas, when a dog with a pancreatic fistula is sham fed, from 3 to 7 cc. of pancreatic juice is obtained, a relatively small amount. I mention that because I doubt whether the nervous secretion of pancreatic juice is very important and because sham feeding is more of a physiologic stimulus than pilocarpine or mecholyl. As far as I know, the effect of sham feeding on pancreatic secretion of the human being has not been determined. The pancreatic juice one obtains from sham feeding is rich in enzymes, but the total output of enzymes does not amount to much. I picture the effect of the vagus nerve on pancreatic secretion when we eat a meal in this way: Vagal impulse affects the zymogen granules in the cell in such a way as to facilitate their solution; then secretin acts to wash these more soluble zymogen products out of the cell. In a normal pancreatic response to a meal both the nervous and the secretin effect operate. What about the usefulness of secretin? Several years ago, when we injected secretin into twenty-six normal medical students, there were three subjects who put out a relatively small total quantity of enzymes. We suspected in them a pancreatic deficiency, so we fed those students a modified Schmitt diet containing 250 Gm. of rare beef tenderloin and 60 cc. of olive oil. We found meat fibers and oil in the stools of all three subjects. The analysis of the stools gave us as much information then as the use of secretin. However, I believe secretin will be used in the diagnosis of absolute pancreatic insufficiency in the same way that histamine is used for such a diagnosis in the case of the stomach at present. The use of secretin may also demonstrate that one enzyme is deficient whereas the others are adequately secreted.

Necrobiosis Lipoidica Diabeticorum

DRS. ALICE HILDEBRAND, HAMILTON MONTGOMERY and E. H. RYNEARSON, Rochester, Minn.: The clinical, pathologic and biochemical observations made in sixty-four cases of necrobiosis lipoidica diabeticorum reported in the literature were reviewed and similar studies made in seven cases seen at the Mayo Clinic were summarized.

Desiccated Hog's Stomach Extract (Ventriculin) in the Treatment of Atrophic Gastritis

DRS. LEON SCHIFF and SANDER GOODMAN, Cincinnati: Five patients with a gastroscopic diagnosis of chronic atrophic gastritis not associated with other gastric disease, anemia, protein deficiency or obvious vitamin deficiency were given desiccated hog's stomach extract (ventriculin) in doses averaging from 30 to 60 Gm. a day. Marked symptomatic improvement occurred and was usually associated with disappearance of the atrophic changes. When the administration of ventriculin was stopped there was usually a return of the gastritic changes which was usually associated with a return of symptoms. These observations suggest that atrophic gastritis may be due to a deficiency of a substance contained in desiccated hog's stomach extract.

DISCUSSION

DR. RUDOLF SCHINDLER, Chicago: This presentation is important because atrophic gastritis is a serious disease not only because of its connection with pernicious anemia and carcinoma but because of its own symptoms, such as weakness and fatigue, which require treatment. Probably not every case of atrophic gastritis is the result of a deficiency. I believe that chronic superficial gastritis may precede formation of a purely inflammatory atrophic gastritis, and it remains doubtful whether they will respond to any treatment. Drs. Palmer and Kirsner and I were able to watch carefully eight cases, and in three the condition did not respond to liver, iron or vitamin therapy. In four cases the gastric mucosa became normal. When the treatment was interrupted, the atrophy returned in two cases. We do not know whether regeneration of gastric mucosa takes place or whether some elements are lacking. Our results are not quite as good as those of Dr. Schiff. It may be that the concentrated liver extract we use is not as potent as the ventriculin. It is worth while to try to treat this disease with substitution therapy, using iron or liver, vitamin or ventriculin.

DR. CLARENCE F. G. BROWN, Chicago: I should like to ask if the authors used gastric mucin in their controls.

DR. E. A. SHARP, Detroit: I believe that the evidence accumulated to show that there is deprivation of some factor may reflect on the lack of information about desiccated hog's stomach. It is known to contain small amounts of vitamin B₂, varying from entire absence to 20 Sherman units per gram. Occasionally this is more concentrated, and sometimes it is absent. Therefore it should be known whether vitamin B₂ was present in the product used and in what amount. With the implication that this deprivation occurs in achlorhydric anemia and that recovery of the mucosa is associated with the administration of ventriculin, I believe further evidence of therapeutic benefit should be accumulated by Dr. Schiff's method and further work should be done on stomach tissue to determine if there is a factor present that we have not considered.

DR. LEON SCHIFF, Cincinnati: We did not use gastric mucin. As to the case in which hydrochloric acid returned, you may recall that this happened a year after treatment was stopped and that the patient failed to relapse after withdrawal of ventriculin. It is therefore possible that the return of hydrochloric acid may have been coincidental. We have naturally been interested in the vitamin content of ventriculin and hope to continue this phase of the problem.

Icterus Complicating Lobar Pneumonia in the Negro

DRS. EDWARD L. TURNER, MICHAEL J. BENT, GUERNEY D. HOLLOWAY and JOHN R. CUFF, Nashville, Tenn.: In a further effort to determine the etiology of icterus in lobar pneumonia and to explain, if possible, the cause of the higher incidence of this complication in Negro patients as compared with white patients, the authors attempted to reproduce and extend Maugeri's experiments. In accord with his studies, rabbits were used as the experimental animal. Insufflations of autogenous blood into the lungs of rabbits produced detectable icterus in only a few of the animals, partially supporting Maugeri's claims. When pneumococci virulent for the rabbit were insufflated into the trachea the animals were overwhelmed too rapidly to produce a picture of pneumonia simulating the human disease. Filtrates of pneumococcus broth cultures combined with autogenous blood when insufflated into the lungs produced tissue

changes in the lungs and liver similar to those seen in human lobar pneumonia. This combination, however, failed in most instances to produce a detectable icterus until after experimental impairment of the liver function.

DISCUSSION

DR. ARTHUR A. HOLBROOK, Milwaukee: Reference was made to Eppinger's observations in this condition. In 1938 I had occasion to visit his clinic. One day on ward rounds he presented a case of lobar pneumonia complicated by jaundice. He pointed out that it was his impression that this complicating factor occurred more frequently when the lobar involvement was in the right lower lobe. I should like to ask if any correlation has been made between lobar distribution and the complicating factor of jaundice.

DR. EDWARD L. TURNER, Nashville, Tenn.: We attempted to correlate the lobar distribution and the complicating factor of jaundice and were unable to do so.

Treatment of Amebiasis by a Combined Method (Oral Administration of Carbarsone and Retention Enemas of Chiniofon)

DRS. JOHN G. MATEER, JAMES I. BALTZ, DONALD F. MARION and ROBERT A. HOLLANDS, Detroit: No single known drug, when used alone in treating amebiasis, has yielded more than about 90 per cent permanent cures with a single course of therapy. A group of 104 patients, some with acute involvement and others carriers, have received only one course of combined treatment, consisting of carbarsone by mouth and simultaneous chiniofon retention enemas given according to a special technic. After treatment careful and repeated stool examinations were made in every case over a period varying from six months to three and one-half years; 97 per cent of these patients remained persistently free from amebas. In no case was there any unfavorable drug reaction.

DISCUSSION

DR. ARTHUR J. ATKINSON, Chicago: How large was the cleansing enema and why did you combine oral and enema treatment instead of giving both drugs orally, since most cases of amebiasis begin in the terminal ileum? Perhaps I have been overcautious about using enemas in amebic dysentery, having seen perforation occur after an enema. Some observers have reported perforation after proctoscopic examination.

DR. JOHN G. MATEER, Detroit: The size of the preliminary saline enema was about 750 cc. We are careful not to overdistend the bowel. The complication referred to by Dr. Atkinson has not been seen in our experience. As regards giving these two drugs simultaneously by mouth, this could probably be done, but I do not know whether it would give as high a percentage of successful end results. I think there is an advantage in getting the concentrated chiniofon solution into intimate contact with the mucous membrane of the large bowel, rather than having the drug diluted and mixed with much fecal material.

Intravital Staining of Malignant Neoplasms by Evans Blue

DRS. ALEXANDER BRUNSCHWIG and T. HOWARD CLARKE. (Introduced by DR. WALTER L. PALMER), Chicago. Evans blue, a nontoxic electronegative azo dye, an isomer of trypan blue, used in blood volume determinations, was injected intravenously into twenty patients with various forms of malignant neoplastic disease. While the dye stained all tissues diffusely in the doses employed, there was in thirteen of the twenty patients selective concentration of the dye in and about the malignant neoplastic foci.

DISCUSSION

DR. CLARENCE BERNSTEIN, Chicago: Several of these pictures resembled those seen in studies of intravital staining with trypan blue and other similar dyes in which the dye was found to be in the lymphatic capillaries. Was the dye in these tumors found to be localized in lymphatics obstructed by the neoplastic tissue?

DR. ALEXANDER BRUNSCHWIG, Chicago: When seen in and about the neoplastic foci the dye is in the macrophages and fibroblasts of the connective tissue in these areas. The dye does not accumulate in the neoplastic cells themselves.

Current Medical Literature

AMERICAN

The Association library lends periodicals to members of the Association and to individual subscribers in continental United States and Canada for a period of three days. Three journals may be borrowed at a time. Periodicals are available from 1930 to date. Requests for issues of earlier date cannot be filled. Requests should be accompanied by stamps to cover postage (6 cents if one and 18 cents if three periodicals are requested). Periodicals published by the American Medical Association are not available for lending but can be supplied on purchase order. Reprints as a rule are the property of authors and can be obtained for permanent possession only from them. Titles marked with an asterisk (*) are abstracted below.

Electrocardiograms of the Aged.—From the general medical clinic of the University of Minnesota Levitt chose 100 patients (from 71 to 93 years of age) with no evident disease of the cardiovascular-renal system, with the exception of the usual changes in the palpable vessels, after a careful physical examination. A painstaking history also elicited no symptoms of cardiovascular-renal disease. The subjects selected were able to perform such tasks as walking two miles, washing clothes, running a household or performing regular duties of a manual nature without dyspnea. None had attacks of nocturnal dyspnea. All patients stated that they were leading an active life, but at a slowed tempo. The complaints of more than 90 per cent of them were prostatic symptoms, carcinoma of the skin, chronic arthritis or diseases of the eye. Sixty-four were men and thirty-six were women. The electrocardiograms of all of them (based on a criteria of RT or ST segment elevated or depressed more than 1 mm. in relation to the iso-electric line, T waves diphasic, longer than 0.1 second, presence of a Pardee Q_s) showed that abnormal, according to the foregoing criteria of abnormality. Twenty-three of the remaining seventy-four patients had premature beats. Left axis deviation was present in fifty-nine and right axis deviation in two. Changes in the ventricular complex are not always identified with a diseased myocardium, and in the presence of severe cardiac muscle damage. Consequently the author states that the pronounced changes found in 26 per cent of his patients should be interpreted with the fact in mind that in rare instances the electrocardiogram is at variance with demonstrable cardiac lesions. He points out that there is sufficient evidence that changes in the electrocardiogram take place normally in the aging heart. These changes include a tendency to decline, for the T wave to be lowered and toward an increase in the duration of the QRS and PR intervals. These moderate changes in the electrocardiogram may or may not indicate that cardiac lesions are present. The author does not regard the alterations of his twenty-six patients simply as a part of the process of senescence. It is believed that they represent some abnormality of the heart.

Organic Heart Disease in School Children.—Rauh reports the incidence of organic heart disease in 85,389 children attending 157 Cincinnati schools. These children were examined

by school physicians, and 1,782 of them had some clinical suggestion of heart disease. When this group was reexamined by four pediatricians (especially interested in cardiology) 633 were found to have normal hearts, 700 to have murmurs which were believed to be only functional or accidental in type and 449 to have definite evidence of heart disease. This last group constituted 25.4 per cent of the patients selected by the school physicians, or 0.53 per cent of the entire number of children. Of the 449 children with heart disease 304 had definite evidence of organic lesions, 109 were classified as possibly having organic disease but requiring further observation to complete the diagnosis and forty-one had extrasystoles. Of the 304 children with organic lesions, a diagnosis of acquired heart disease, probably rheumatic in origin, was made in 55 per cent and congenital lesions in 45 per cent. Acquired heart disease was more prevalent in the Negro than in the white children. It occurred more frequently in girls than in boys, and more often in children living under poorer economic conditions. The incidence of congenital heart disease was independent of race or sex and was fairly equally distributed among the different age groups studied. A comparison of the results of this study with previous school surveys indicates that there are wide variations of incidence in different localities. The statement that 80 per cent of the acquired lesions are rheumatic in origin is true only in areas in which rheumatic fever is prevalent and severe and cannot be universally employed as a distribution figure.

Development of Tuberculosis in Infected Children.—The data that Pope and his associates present were based on the tuberculin tests of 400,000 school children in the Chadwick Clinics between 1924 and 1934, the reexamination of certain groups of these children and the cases of pulmonary tuberculosis subsequently reported in the entire group. The subsequent reported morbidity and mortality from tuberculosis has been determined to the end of 1936 and rates have been computed on the basis of the original reaction. Among the reactors the morbidity from the adult type of tuberculosis has been about four times that in the nonreactors. The death rate has been three times as great in the reactors, and the case fatality essentially the same in the two groups. The cumulative morbidity from tuberculosis in children reexamined annually for from ten to eleven years was more than 6 per cent. This rate was approximately twice as high in girls as in boys and was substantially higher among reactors than among nonreactors. Among reactors it was more than three times as high in those with originally positive roentgenograms. The tuberculosis morbidity among children with a history of a family exposure to the disease was two and a half times that in children without known exposure. Age specific morbidity rates in the series show that significant tuberculosis is infrequent in school children less than 10 years of age and that the incidence rises rapidly after this age, much more rapidly in girls than in boys.

Food Poisoning Due to Staphylococci.—Slocum and Linden discuss the occurrence of twenty outbreaks of food poisoning apparently due to staphylococci, all of which followed the consumption of "ready to eat" hams or tongue. In these twenty outbreaks at least 1,028 individuals were affected. Two deaths occurred, neither of which was attributed directly to food poisoning but to other complicating conditions. In many of the outbreaks there is little evidence to indicate the source of

the staphylococci or when, in the process of manufacture, distribution and handling prior to consumption, the organisms entered the products. The public health problem presented by the staphylococcus food poisoning, incriminating "ready to eat" ham and related salt-cured meat products, appears to be as great as that presented by custard bakery products. A study of thirty-seven strains of staphylococci isolated from food involved in eleven outbreaks demonstrated that the majority of the strains had lost their ability to produce enterotoxin and a positive Stone reaction during storage on laboratory mediums. A fundamental difference between the enterotoxic and nonenterotoxic strains studied seems to be indicated by the fact that they differ markedly in agglutinability by normal horse serum.

Roentgen Treatment of Sinus Infections.—To determine which type of sinusitis is amenable to roentgen therapy, Fitor and Waters adopt a classification which has as its basis the various microscopic changes observed in the different stages of the infection. 1. Most cases of acute sinusitis clear up under the usual treatment of inhalations, packing, suction and washings. Because of this, as well as the tension in the affected sinus, roentgen treatment is not indicated. After good drainage has been established, one or two small roentgen doses may hasten convalescence. 2. In subacute sinusitis when examined roentgenologically after washing, the antrums are observed to have extremely thick membranes enclosing a small air space. Unless treated by radical operation or irradiation, they often become chronically infected. The membrane, being filled with lymphocytes and a smaller number of polymorphonuclears, is markedly sensitive to the rays. 3. Cases of chronic sinusitis with thickened membrane, but without polyp formation, are usually due to failure to consult a rhinologist early enough. Others have not been adequately treated or have resisted the usual forms of treatment. This type of sinusitis is also definitely sensitive, being only slightly less so than the subacute group. Microscopic section shows dense infiltration of the submucous area by large numbers of lymphocytes and a moderate number of polymorphonuclear and plasma cells. A favorable reaction to irradiation can be expected because of the cellular infiltration of the submucosa. 4. Chronic sinusitis with much scar tissue or polyp formation constitutes a later developmental type in the course of sinus disease. Because of the presence of scar tissue and relatively little cellular infiltration this group is less sensitive than the preceding, although early scar tissue and polyp formation may be affected moderately by fractional highly filtered radiation, whereas later fibrosis and polyposis is affected but slightly if at all. Microscopic section shows fibrosis with relatively little leukocytic infiltration. 5. Atrophic sinusitis is resistant to the rays. Allergic cases of sinusitis are unlikely to respond to irradiation unless there is associated infection. Lymphoid hyperplasia in the nasopharynx in children in association with thickened sinus membranes responds exceedingly well under

irradiation. Good drainage in subacute infections and open ostiums in the chronic group are most desirable. The removal of infected tonsils and adenoids, submucous resections and nasal polypectomies have been found to be of primary importance for permanent relief of this distressing condition. Irradiation is worthy of trial in these difficult cases because many of the sinus membranes contain lymphocytes on microscopic examination. The authors believe that about 70 per cent of properly selected cases of sinusitis can be cured (complete disappearance of symptoms with clear sinuses) or markedly improved (complete disappearance of symptoms with slightly opaque sinuses) by irradiation. The use of prolonged and intensive therapy is not necessary. The authors have had excellent results after four biweekly doses of 100 roentgens each. At times it has been necessary to use 600 roentgens over a period of three weeks to obtain the maximal desirable result. This dose, delivered at 125 kilovolts, 5 milliamperes, 35 cm. focal skin distance and filtered through 4 mm. of aluminum, is about 45 per cent of an erythema dose under these circumstances. Epilation is prevented by covering the hair, eyebrows and eyelashes with strips of lead. In children the dental buds in the maxilla are similarly protected. Fractional doses give the operator better control, tend to avoid possible unpleasant sequelae, such as headache, and will permit the administration of a larger dose should this be necessary.

Radium Therapy in Hodgkin's Disease.—Sayago reports a case of Hodgkin's disease which demonstrates that small quantities of radium, not more than 160 mg., at a distance of from 6 to 7 cm. from the surface of the skin, is enough to produce satisfactory results even in cases in which there are enlarged lymph nodes deep in the chest. The low intensity of radium compared with roentgen radiation is a disadvantage in this application, as the distance to the skin cannot be increased very much unless large quantities of radium are used. In this case a skin distance of not more than 6 cm. was sufficient to cause large nodes situated within the chest to disappear. The nodes within the chest were irradiated through two skin ports, one over the cervical region and the other over the anterior part of the chest. Notwithstanding the great distance from the cervical region to the lower nodes within the chest there was a marked diminution in size before the second application was made.

Endocrines and Spermatogenesis.—Hotchkiss states that there is evidence of the close relationship of spermatogenesis and the gonadotropic hormones. Appropriate use of gonadotropic substance can cause hyperplasia and hypertrophy of testicular cells in hypophysectomized animals which appear to be closely related to the onset of spermatogenesis in seasonal breeders. Certain seminal deficiencies may be the result of minor infarctions of the endocrines, particularly the pituitary. The author has on record several well controlled cases which

have demonstrated gradual but progressive increases in sperm counts following prolonged use of gonadotropic substance. Three cases are presented illustrating improvement coincidental to the use of the gonadotropic principle.

Ammonium Bicarbonate in Wound Healing.—In a further analysis of the secretions of surgical maggots, Robinson found that ammonium bicarbonate is present in comparatively large quantities. In solution ammonium bicarbonate has an alkalinity of pH 7.7, corresponding roughly with that of maggot excretions. Wounds treated with maggots tend to have this same alkalinity. Preliminary tests were made with commercial ammonium bicarbonate to determine what effect the pure solution would have when applied to wounds of dogs and rabbits having persistent discharging sores, chiefly on the back and legs. A 2 per cent solution of ammonium carbonate or bicarbonate in sterile water was made up and applied to the wounds in a series of comparative tests. The wounds were thoroughly moistened several times a day with either of these solutions. The wounds healed with the formation of little scar tissue. In later studies with gauze packs saturated with 1 or 2 per cent concentrations of either of the two ammonium compounds, healing was promoted in purulent and indolent wounds. In purulent conditions, such as chronic osteomyelitis, diabetic and varicose ulcers, otitis media and infected lacerations, ammonium bicarbonate solution caused an improvement in the wound similar to that produced by maggots.

Nondysenteric Intestinal Amebiasis.—Sapero investigated only patients with intestinal amebiasis who gave neither a present nor a past history of dysentery. The cases comprised both symptomless carriers of *Endamoeba histolytica* and infected individuals with complaints of varying severity. Control observations were made whenever feasible. Only those symptoms and signs were ascribed to *Endamoeba histolytica* after other possible causes had been ruled out. In all, 216 cases of nondysenteric amebiasis were studied, of which 100 were found to show symptoms. A study of the symptomatology of 106 apparently healthy men harboring *Endamoeba histolytica* showed forty-six, or 43.4 per cent, to have symptoms. A control group of 108 cases negative for intestinal protozoa revealed only eight, or 7.4 per cent, to have complaints. Of the 106 men harboring *Endamoeba histolytica* only 13.2 per cent had complaints of any appreciable severity. Of 236 individuals harboring various intestinal protozoal species, but not *Endamoeba histolytica*, the percentage with symptoms was similar to that found in the nonparasitized group, with the exception of *Diendamoeba fragilis*, as 27.3 per cent of forty-four persons presented symptoms. A study of the blood of sixty-one apparently healthy carriers of *Endamoeba histolytica* showed no significant differences from the results obtained in a control group of an equal number of individuals not harboring the parasite. Despite the apparent trivial nature of the complaints of the ambulatory group of patients a study of various hospitalized groups showed that a considerable number of nondysenteric amebic infections are severe enough to require hospitalization. In forty-seven such cases the condition was so obscure that only the finding of the parasite in the stool led to the proper diagnosis, and in these specific antamebic treatment gave good results where other methods had failed. The complaints were primarily referable to the gastrointestinal tract, yet without blood and mucus in the stools and usually without intestinal abnormalities which might suggest an amebic process. Complaints referable to both the upper and the lower gastrointestinal tract appeared with equal frequency. Com-

plaints referable to other systems were seldom encountered. Chronicity, recurrence and mildness of the symptoms were characteristic features. A symptom complex simulating subacute or chronic appendicitis was the most commonly observed syndrome in this series of nondysenteric cases of amebiasis.

Fateful Periods of Tuberculosis-Infected Individual.—Holló maintains that the fate of the tuberculous individual depends largely on his behavior during certain, usually short, periods of life. Under physiologic conditions, infection with tuberculosis as a rule does not involve serious danger. If, however, resistance is broken by some additional factor infection will progress. In most cases the tuberculosis is the effect of certain factors besides the infection. Malnutrition, overexertion and lack of pure air are the chief catalysts of tuberculosis, to which one may add the lack of hygienic culture, especially in groups living in an infected environment. In the years around the Great War the start of tuberculous disease could but occasionally be traced to some well defined indiscretion in life habits. Now the connection between some harmful influence and the apparent start of the disease is obvious in most cases. Among the events which in the author's experience have given rise to manifest disease or to an exacerbation of a quiescent condition are college examinations, military service, training for athletic competition, mountain climbing, camping, excessive sunbaths, overwork, exhaustion, nursing of a gravely ill parent, love affairs, abortion, childbirths in quick succession, divorce, death in the family, weight reducing cure, tonsillectomy, drastic antisyphilitic treatment and intercurrent diseases. Infancy and senility rather than puberty represent the most susceptible periods for tuberculosis.

Basal Tuberculosis.—Busby says that a review of the literature shows that the outlook for basal tuberculosis is unfavorable. He found that among 3,597 new patients admitted to the Detroit Municipal Tuberculosis Sanatorium 795 were children. Among the adults the lower lobes were involved in 1.8 per cent, while among the children the incidence was about 20 per cent. The adult cases form the basis of the present study. The duration of symptoms before diagnosis or hospitalization in the adult cases varied from two weeks to several years. Although the average duration of symptoms was 5.5 months, the disease of forty was moderately or far advanced, thirty-one had cavitation varying from 1 to 9.5 cm. in diameter and twenty-two showed evidence of spread to the contralateral lung. The time of spread varied from three months to two years, but in the majority it was between three and six months. From a comparison of basal with initial disease in the upper half of the lung in an equal and comparable number of persons, the disease of twenty-two of the former and twelve of the latter spread to the same or to the contralateral lung. From this it appears that basal lesions tend to early and rather large cavity formation and to earlier and more frequent spread than initial lesions in the upper half of the lung. The results in five cases treated with bedrest alone indicate that this therapy is not safe or justified for basal lesions. Six of the eleven patients with moderately advanced involvement who received phrenic surgery alone recovered, while three of eight who received

artificial pneumothorax alone recovered. This suggests that in minimal and moderately advanced involvement crushing of the phrenic nerve might be tried before artificial pneumothorax is induced. In the far advanced cases no benefit was derived from phrenic nerve surgery alone. Of the twenty-two patients receiving pneumothorax alone six recovered, while of the twenty-eight who received both pneumothorax and phrenic surgery twenty-one recovered. This suggests that in far advanced cases artificial pneumothorax should be attempted first with a view to adding phrenic surgery relatively soon. The difference in favorable results warrants the use of both procedures whenever possible. The author states that patients with disease of the lower lobes, when adequately treated, behave much the same as patients with disease elsewhere in the lung.

Influence of Vitamin Deficiencies on Other Diseases.—Youmans reviews the knowledge of the influence of vitamin deficiency on other diseases. From the review it is apparent that there is little reliable scientific evidence of the effect of vitamin deficiencies on disease and therefore little justification for the current widespread use of vitamins as therapeutic agents in a great number of illnesses. This does not mean that such an influence is lacking or that one should neglect the presence of deficiencies and fail to employ such measures as are needed to ensure adequate nutrition. On the contrary there is good reason to believe that vitamin deficiencies occur as complications of many diseases and modify their course and outcome. For the present the influence of vitamin deficiencies must be considered to be that which might reasonably be expected of a poor nutrition generally, without reference to specific and clearly demonstrated effects.

Picrotoxin for Barbiturate Poisoning.—A review of clinical reports of twenty-two cases in which picrotoxin was used indicates to the Reifensteins and their collaborators that picrotoxin, properly employed, is the most successful antidote for barbiturate poisoning. They add two cases to those already recorded. One patient recovered after the ingestion of what they believe is the largest dose of barbitol yet reported in a case in which picrotoxin was employed. The first case of acute barbiturism was brought about by the ingestion of 16.3 Gm. (245 grains) of barbitol, with recovery after the use of 314 mg. of picrotoxin. The other instance of recovery occurred after the ingestion of from 0.5 to 1 Gm. (7½ to 15 grains) of secenal and the therapeutic use of 24 mg. of picrotoxin.

Sulfanilamide for Pulmonary Tuberculosis.—Because of the controversial experimental background and because they were desirous of determining what effect sulfanilamide would have on a chronic disease, Freilich and his co-workers used it for twenty male and fifteen female patients with moderate and far advanced pulmonary tuberculosis. Treatment with the drug continued from ten to fifteen weeks. The drug was administered

orally in 10 grain (0.65 Gm.) doses three times a day, with equivalent amounts of sodium bicarbonate. This was gradually increased to 20 grains (1.3 Gm.) three times a day over a period of one month, and for the ensuing six to ten weeks each patient received this maximal daily dose. No other medication was given, and magnesium sulfate, salicylates and undue exposure to sunlight were carefully avoided. Other than an initial psychic stimulus because something new was being used, the sulfanilamide did not appear to cause any physical or subjective improvement of any of the patients. Toxic headaches were plentiful. Stopping the sulfanilamide caused them to disappear only to recur when the drug was again taken. That this reaction was not of psychogenic origin was established by the fact that when lactose tablets of the same size, shape and color as the sulfanilamide tablets were substituted the headaches did not recur. Cyanosis was common but was of no great significance.

Bismuth Therapy in Latent Plumbism.—Epstein presents two cases in which a painter and a smelter worker showed signs and symptoms of lead poisoning followed the administration of a bismuth compound in the treatment of a syphilitic infection. It is suggested that bismuth may replace the lead stored in the bones and tend to the mobilization of lead, with the development of such symptoms as cramps and a lead line. Prophylactic treatment of lead poisoning in those exposed to the influence of the metal may decrease the incidence of untoward reactions following bismuth therapy.

Dangers of Cosmetics.—Wolcott reviews selected literature on the composition of and dangers in the use of important cosmetics. The majority of injuries from cosmetics at present belong in the field of allergic dermatoses. The aniline dyes and coal tar derivatives, in particular the paraphenylenediamine group, are the most serious offenders. Hair dyes, especially preparations for the eyelashes, are extremely dangerous. A new field of cosmetic manufacture, that of synthetic perfumes, is giving rise to many dermatoses. Nail polishes, although relatively innocuous, may cause extensive physical disturbance of the nails. Reference is made to the federal Food, Drug and Cosmetic Act of 1938, designed to regulate interstate and foreign commerce in these items. It is unfortunate that the law does not require listing of ingredients on the label, because in this manner potentially dangerous substances would be known to the consumer and, secondarily, racketeering prices for ingredients of low actual cost would be reduced.

Diseases of Nails.—Fox says there is evidence that diseases of the nails, excluding the pyogenic and fungous infections and changes associated with the inflammatory dermatoses, are often produced by endocrine dysfunction, particularly hypothyroidism and hypopituitarism. Systemic diseases, such as the anemias, avitaminosis and the endocrine disturbances, may present important changes of the nails. This report is based on the study of thirty cases of onycholysis. Of the thirty patients, twenty-eight were women and two were men. Twenty-seven had multiple

separations and three had separation of a single nail. Twenty had low basal metabolic rates and fifteen of these had other symptoms suggesting hypothyroidism, such as a tendency to gain weight easily, a requirement of eight to ten hours' sleep, easy fatigability, excessive susceptibility to cold weather, dryness of the skin and hair and brittle nails. Several had winter pruritus (pruritus hiemalis), with dryness of the skin over the entire body and in cool weather annoying itching, which was aggravated by frequent bathing. One patient had psoriasis of the elbows but there was no evidence of psoriasis of the nails; another had lichen planus without any inflammatory process of the nails, and one had recovered from lichen planus several months previously. Twenty-one showed improvement on thyroid medication, three did not improve and three were not observed for a sufficient period to determine the final results. The author tabulates the data in his thirty cases and then reviews the literature on the concurrence of abnormality of the nails with disorders of the thyroid and other endocrine dysfunctions. He concludes that the influence of the hormones on the development of the skin and its appendages should receive more consideration from the dermatologist.

Cerebral Complications Following Surgery.—Behrend and Riggs show that the various cerebral complications encountered after surgical operation may be the result of cerebral anoxia resulting from acute general circulatory collapse precipitated by the anesthetic, plus the trauma of operation, in persons whose margin of circulatory reserve has been reduced by a masked chronic circulatory insufficiency. The brain and viscera of twenty-one patients dying after operation at the Philadelphia General Hospital have been examined. In each case symptoms referable to the cerebrum complicated the post-operative course. Preoperatively only six of the patients could be considered poor surgical or anesthetic risks. The diversity of symptoms reported by other observers is a strong argument against the theory of cerebral vascular accident. In the twenty-one cases the symptoms (psychic disturbances, prolonged coma, convulsions, focal paralyses and death during operation) were usually those suggesting diffuse involvement of the entire brain

and, as a rule, at some period more than one symptom was present in each case. Fourteen of the patients in the series surviving longer than twelve hours died with hyperpyrexia unexplainable on an infectious basis. Gross inspection of the brains of the twenty-one patients lent no support to the theory of infarction as a result of embolism. Microscopically, Courville's theory of widespread cellular degeneration throughout the brain, regardless of the type of clinical manifestation of cerebral involvement, was confirmed. Generalized capillary damage with widespread parenchymatous degeneration due to pericellular and interstitial edema was present in every case. Although the edema due to capillary damage was universal, the cellular degeneration was most marked in the association areas of the cortex, the sympathetic ganglions in the gray matter around the third and fourth ventricles and lenticular nucleus, the dentate and Purkinje cells of the cerebellum and the region of the inferior olive in the medulla. As these are the areas that Chornyak found most severely affected in animals subjected to atmospheres deficient in oxygen, this would further suggest that Courville's theory of asphyxia as a factor in the production of cerebral symptoms after anesthesia might be extended to include not only nitrous oxide anesthesia but all forms of anesthesia. Patients who survived less than forty-eight hours showed no evidence of reaction indicating attempted repair. Eight of the ten patients who survived from two to nine days showed focal areas of glial and phagocytic activity, suggesting beginning repair and scar formation. The cerebral symptoms were not related to the duration or type of anesthesia. Since edema and congestion not only of the brain but also of the viscera were observed at necropsy, it would seem that the cerebral degeneration is more reasonably attributable to the combined effect of anesthesia and operation on an impaired general circulatory efficiency with secondary reflection in the brain than to a direct selective anoxia of the brain cells alone.

Rectal Carcinoma in the Young.—The factors which influence the prognosis of carcinoma of the rectum and of the rectosigmoid in persons 30 or less years of age are multiple, although the most important are the ability of the patient to withstand the effects of removal and the presence or absence of metastasis. The latter factor closely parallels the grade of tumor as classified by Broders. Mayo and Madding review 116 cases of carcinoma of the rectum and of the rectosigmoid in persons 30 or less years of age. Of the patients with grade 1 carcinoma subjected to some form of curative operation, 75 per cent survived the five year period. There was a decrease of 28 per cent for the next grade, and only 10 per cent of the patients with grade 3 tumors survived the five year period. The data support the contention of other reports that carcinoma in young persons is usually of a higher grade than in older persons. Patients with lesions situated low in the rectum for which some form of posterior resection was performed were found to have an average postoperative life of 5.8 years, with an operative mortality of only 2.7 per cent. The combined operative mortality for the entire group treated by resection was 12.3 per cent.

artificial pneumothorax alone recovered. This suggests that in minimal and moderately advanced involvement crushing of the phrenic nerve might be tried before artificial pneumothorax is induced. In the far advanced cases no benefit was derived from phrenic nerve surgery alone. Of the twenty-two patients receiving pneumothorax alone six recovered, while of the twenty-eight who received both pneumothorax and phrenic surgery twenty-one recovered. This suggests that in far advanced cases artificial pneumothorax should be attempted first with a view to adding phrenic surgery relatively soon. The difference in favorable results warrants the use of both procedures whenever possible. The author states that patients with disease of the lower lobes, when adequately treated, behave much the same as patients with disease elsewhere in the lung.

Influence of Vitamin Deficiencies on Other Diseases.—Youmans reviews the knowledge of the influence of vitamin deficiency on other diseases. From the review it is apparent that there is little reliable scientific evidence of the effect of vitamin deficiencies on disease and therefore little justification for the current widespread use of vitamins as therapeutic agents in a great number of illnesses. This does not mean that such an influence is lacking or that one should neglect the presence of deficiencies and fail to employ such measures as are needed to ensure adequate nutrition. On the contrary there is good reason to believe that vitamin deficiencies occur as complications of many diseases and modify their course and outcome. For the present the influence of vitamin deficiencies must be considered to be that which might reasonably be expected of a poor nutrition generally, without reference to specific and clearly demonstrated effects.

Picrotoxin for Barbiturate Poisoning.—A review of clinical reports of twenty-two cases in which picrotoxin was used indicates to the Reifenstein and their collaborators that picrotoxin, properly employed, is the most successful antidote for barbiturate poisoning. They add two cases to those already recorded. One patient recovered after the ingestion of what they believe is the largest dose of barbitol yet reported in a case in which picrotoxin was employed. The first case of acute barbiturism was brought about by the ingestion of 16.3 Gm. (245 grains) of barbitol, with recovery after the use of 314 mg. of picrotoxin. The other instance of recovery occurred after the ingestion of from 0.5 to 1 Gm. (7½ to 15 grains) of secional and the therapeutic use of 24 mg. of picrotoxin.

Sulfanilamide for Pulmonary Tuberculosis.—Because of the controversial experimental background and because they were desirous of determining what effect sulfanilamide would have on a chronic disease, Freilich and his co-workers used it for twenty male and fifteen female patients with moderate and far advanced pulmonary tuberculosis. Treatment with the drug continued from ten to fifteen weeks. The drug was administered

orally in 10 grain (0.65 Gm.) doses three times a day, with equivalent amounts of sodium bicarbonate. This was gradually increased to 20 grains (1.3 Gm.) three times a day over a period of one month, and for the ensuing six to ten weeks each patient received this maximal daily dose. No other medication was given, and magnesium sulfate, salicylates and undue exposure to sunlight were carefully avoided. Other than an initial psychic stimulus because something new was being used, the sulfanilamide did not appear to cause any physical or subjective improvement of any of the patients. Toxic headaches were plentiful. Stopping the sulfanilamide caused them to disappear only to recur when the drug was again taken. That this reaction was not of psychogenic origin was established by the fact that when lactose tablets of the same size, shape and color as the sulfanilamide tablets were substituted the headaches did not recur. Cyanosis was common but was of no great significance.

Bismuth Therapy in Latent Plumbism.—Epstein presents two cases in which a painter and a smelter worker showed signs and symptoms of lead poisoning followed the administration of a bismuth compound in the treatment of a syphilitic infection. It is suggested that bismuth may replace the lead stored in the bones and tend to the mobilization of lead, with the development of such symptoms as cramps and a lead line. Prophylactic treatment of lead poisoning in those exposed to the influence of the metal may decrease the incidence of untoward reactions following bismuth therapy.

Dangers of Cosmetics.—Wolcott reviews selected literature on the composition of and dangers in the use of important cosmetics. The majority of injuries from cosmetics at present belong in the field of allergic dermatoses. The aniline dyes and coal tar derivatives, in particular the paraphenylenediamine group, are the most serious offenders. Hair dyes, especially preparations for the eyelashes, are extremely dangerous. A new field of cosmetic manufacture, that of synthetic perfumes, is giving rise to many dermatoses. Nail polishes, although relatively innocuous, may cause extensive physical disturbance of the nails. Reference is made to the federal Food, Drug and Cosmetic Act of 1938, designed to regulate interstate and foreign commerce in these items. It is unfortunate that the law does not require listing of ingredients on the label, because in this manner potentially dangerous substances would be known to the consumer and, secondarily, racketeering prices for ingredients of low actual cost would be reduced.

Diseases of Nails.—Fox says there is evidence that diseases of the nails, excluding the pyogenic and fungous infections and changes associated with the inflammatory dermatoses, are often produced by endocrine dysfunction, particularly hypothyroidism and hypopituitarism. Systemic diseases, such as the anemias, avitaminosis and the endocrine disturbances, may present important changes of the nails. This report is based on the study of thirty cases of onycholysis. Of the thirty patients, twenty-eight were women and two were men. Twenty-seven had multiple

separations and three had separation of a single nail. Twenty had low basal metabolic rates and fifteen of these had other symptoms suggesting hypothyroidism, such as a tendency to gain weight easily, a requirement of eight to ten hours' sleep, easy fatigability, excessive susceptibility to cold weather, dryness of the skin and hair and brittle nails. Several had winter pruritus (*pruritus hiemalis*), with dryness of the skin over the entire body and in cool weather annoying itching, which was aggravated by frequent bathing. One patient had psoriasis of the elbows but there was no evidence of psoriasis of the nails; another had lichen planus without any inflammatory process of the nails, and one had recovered from lichen planus several months previously. Twenty-one showed improvement on thyroid medication, three did not improve and three were not observed for a sufficient period to determine the final results. The author tabulates the data in his thirty cases and then reviews the literature on the concurrence of abnormality of the nails with disorders of the thyroid and other endocrine dysfunctions. He concludes that the influence of the hormones on the development of the skin and its appendages should receive more consideration from the dermatologist.

Cerebral Complications Following Surgery.—Behrend and Riggs show that the various cerebral complications encountered after surgical operation may be the result of cerebral anoxia resulting from acute general circulatory collapse precipitated by the anesthetic, plus the trauma of operation, in persons whose margin of circulatory reserve has been reduced by a masked chronic circulatory insufficiency. The brain and viscera of twenty-one patients dying after operation at the Philadelphia General Hospital have been examined. In each case symptoms referable to the cerebrum complicated the post-operative course. Preoperatively only six of the patients could be considered poor surgical or anesthetic risks. The diversity of symptoms reported by other observers is a strong argument against the theory of cerebral vascular accident. In the twenty-one cases the symptoms (psychic disturbances, prolonged coma, convulsions, focal paralyses and death during operation) were usually those suggesting diffuse involvement of the entire brain

and, as a rule, at some period more than one symptom was present in each case. Fourteen of the patients in the series surviving longer than twelve hours died with hyperpyrexia unexplainable on an infectious basis. Gross inspection of the brains of the twenty-one patients lent no support to the theory of infarction as a result of embolism. Microscopically, Courville's theory of widespread cellular degeneration throughout the brain, regardless of the type of clinical manifestation of cerebral involvement, was confirmed. Generalized capillary damage with widespread parenchymatous degeneration due to pericellular and interstitial edema was present in every case. Although the edema due to capillary damage was universal, the cellular degeneration was most marked in the association areas of the cortex, the sympathetic ganglions in the gray matter around the third and fourth ventricles and lenticular nucleus, the dentate and Purkinje cells of the cerebellum and the region of the inferior olive in the medulla. As these are the areas that Chornyak found most severely affected in animals subjected to atmospheres deficient in oxygen, this would further suggest that Courville's theory of asphyxia as a factor in the production of cerebral symptoms after anesthesia might be extended to include not only nitrous oxide anesthesia but all forms of anesthesia. Patients who survived less than forty-eight hours showed no evidence of reaction indicating attempted repair. Eight of the ten patients who survived from two to nine days showed focal areas of glial and phagocytic activity, suggesting beginning repair and scar formation. The cerebral symptoms were not related to the duration or type of anesthesia. Since edema and congestion not only of the brain but also of the viscera were observed at necropsy, it would seem that the cerebral degeneration is more reasonably attributable to the combined effect of anesthesia and operation on an impaired general circulatory efficiency with secondary reflection in the brain than to a direct selective anoxia of the brain cells alone.

Rectal Carcinoma in the Young.—The factors which influence the prognosis of carcinoma of the rectum and of the rectosigmoid in persons 30 or less years of age are multiple, although the most important are the ability of the patient to withstand the effects of removal and the presence or absence of metastasis. The latter factor closely parallels the grade of the tumor as classified by Broders. Mayo and Madding review 116 cases of carcinoma of the rectum and of the rectosigmoid in persons 30 or less years of age. Of the patients with grade 1 carcinoma subjected to some form of curative operation, 75 per cent survived the five year period. There was a decrease of 28 per cent for the next grade, and only 10 per cent of the patients with grade 3 tumors survived the five year period. The data support the contention of other reports that carcinoma in young persons is usually of a higher grade than in older persons. Patients with lesions situated low in the rectum for which some form of posterior resection was performed were found to have an average postoperative life of 5.8 years, with an operative mortality of only 2.7 per cent. The combined operative mortality for the entire group treated by resection was 12.3 per cent.

Traumatic Appendicitis.—Pease asserts that traumatic appendicitis is a definite clinical entity and as such must be recognized not only by physicians but also by the courts in questions of litigation and compensation. Cases of so-called traumatic appendicitis can be found in the literature. It is nevertheless hard to believe. The trauma of traumatic appendicitis should not be thought of as a direct injury to the appendix as in the case of the liver and spleen but as trauma applied to the abdominal wall and its contents, which consist not only of solid organs but of gas and fluid as well. This means that force can be transmitted in all directions and therefore that the contents of the cecum and even the ascending colon can be forced into the appendix. The appendix can be so distended as a result of this force as possibly to rupture the mucosa and thus offer an avenue for the ever present infectious organisms to invade the wall of the appendix and start an acute inflammatory condition. In the presence of a fecalith in the lumen of the appendix it can be reasoned that this same trauma can cause the fecalith to injure the mucosa of the appendix and thus leave an avenue for a source of infection. This same fecalith or foreign body can block the exit of gas and contents from the appendix and permit swelling and possible perforation to result.

Cystic Fibrosis of Pancreas.—Andersen states that cystic fibrosis of the pancreas is a disease entity which can be diagnosed with probability on clinical grounds and proved by the assay of pancreatic enzymes in the duodenal juice. The diagnosis may be suggested on the basis of neonatal onset, large foul stools, failure to gain in the presence of a good appetite while taking an adequate diet, a tendency to repeated or chronic respiratory infections and a history of similar disease in siblings. All cases of bronchiectasis or xerophthalmia in infancy should be strongly suspected. As to treatment, the best advice is to give from 20 to 40 per cent more than the estimated caloric requirement of a celiac diet and to modify this by the use of whole milk mixed with pancreatin. Vitamin A should be administered generously.

Vitamin K and Hemorrhage.—Waddell and Guerry believe that a direct relation exists between the prothrombin content of the blood and the bleeding that occurs in hemorrhagic dis-

ease of the newborn. They report four cases of subclinical hemorrhagic disease and one case of spontaneous bleeding, all successfully treated with vitamin K concentrate. The hypothesis is advanced that marked prothrombin deficiency is the immediate cause of the syndrome known as hemorrhagic disease of the newborn and that subclinical cases without spontaneous bleeding are of frequent occurrence. The same condition of bleeding is probably present at birth and may in fact account for many instances of intracranial hemorrhage associated with normal labor and delivery. It seems that intracranial bleeding associated with normal delivery can be lessened by preventive treatment, that is treating the infant with vitamin K through the mother. The authors have found synthetic vitamin K (2-methyl-1, 4-naphthoquinone) to be efficacious.

Vitamin A and Dark Adaptation.—Lewis and Haig determined the minimal light threshold after complete dark adaptation of fifty-three infants ranging in age from 1½ to 13 months. These infants were on four different diets. The diets were given for periods varying from three to ten months. The results of the dark adaptation tests were within normal limits for all four groups of infants. Thus, infants receiving only from 135 to 200 vitamin A units daily had as low a threshold for vision in the dark as infants receiving an average diet supplemented by 17,000 vitamin A units. It should also be added that the infants in the low vitamin A group gained weight just as well as those in the high vitamin A group and were no more susceptible to infections. As the average diet contains approximately twelve times as many units of vitamin A as were contained in the low vitamin A diet, it is apparent that there is a large margin of safety in the infant's diet with respect to its vitamin A content. Therefore it seems unnecessary to supplement the average diet of infants with special preparations containing vitamin A. Three infants, two of whom had eczema, received as a substitute for milk a proprietary preparation containing soy bean, starch and olive oil. This product is almost devoid of vitamin A. In from three to four weeks these infants manifested poor dark adaptation. The addition of 120 units of vitamin A resulted in normal dark adaptation in two of these infants. When a single large dose of vitamin A, from 30,000 to 50,000 units, was given these two infants who had high threshold values, a prompt response occurred; dark adaptation returned to normal in forty minutes in one infant and in sixty-five minutes in the other infant. In the period during which the three infants on the soy bean diet had poor dark adaptation, they gained well in height and in weight and were no more susceptible to infections than infants receiving large quantities of vitamin A. It is concluded that they had a latent or subclinical form of vitamin A deficiency which became evident only as a result of the dark adaptation tests.

Clinical Study of Hypnotics.—Meyers and his co-workers determined the influence of therapeutic doses of hypnotics on the length of sleep, the time of its onset, the number of gross movements during sleep and changes in pulse rate, respiratory rate and blood pressure. Subjects for the experiments were patients who were free from pain and were not having treatment which might have influenced their sleep. None of these patients received opiates or sedatives as part of their daytime treatment. The subjects received their usual ward routine care during the day, but from 9 p. m. to 8 a. m., and longer when necessary, they were kept in a separate room and were under the constant observation of a nurse especially trained for the study. The two beds used for the experiment were attached to actographs. The drugs used were a placebo, N-tolyl-butyl-ethyl-barbital, neonal, a urea derivative, sodium pentobarbital and sodium amylal. Various doses within the therapeutic range were administered. Each of these drugs was pressed into tablets, all having a similar appearance so that the subjects would not know what medication they were receiving. Twelve patients were studied for a total of 219 nights of observation. Each subject remained in the sleep room for a minimum of fourteen days and a maximum of twenty-six days. The placebos and the hypnotics were given in no definite order but each patient received the placebo at least four times during the course of study. The authors find that the time of onset of sleep was not more rapid after the use of any one hypnotic. The average length of sleep was increased about twenty minutes. The sleep pattern, as measured by the number of gross movements made during sleep, was not changed except in four cases of congestive heart failure. In these instances the hypnotics increased the number of movements during sleep. The pulse rate, respiratory rate and blood pressure in the twelve subjects with normal cardiovascular mechanisms was consistently depressed by the hypnotics, while the four patients with congestive heart failure showed but little change.

Effect of Fluorides on Salivary Amylase.—The fluorides sodium, potassium and ammonium fluoride and fluosilicate were found by McClure to have no effect on the activity of salivary amylase in concentrations varying from 1.7 to 8,550 parts per million of fluorine present in 1:10 dilutions of salivas which stood for one hour in the cold prior to testing of the amylolytic property. The same fluorides when present in the enzyme-substrate mixture during the digestion period, in concentrations varying from 0.76 to 760 parts per million of fluorine in the substrate, had no final effect on enzyme activity. The salivas of school children whose drinking water contained an average

of 1.8 parts per million of fluorine showed no differences in amylolytic action from a similar group of salivas obtained under similar conditions from school children whose drinking water was free from fluoride.

Appendicostomy for Chronic Ulcerative Colitis.—Compared to ileostomy or colostomy in chronic ulcerative colitis, Cushman and Kilgore state that appendicostomy is an operation carrying little or no risk, it is devoid of the major unpleasant aspects of ileostomy, conserving instead of losing fluid and salts, and it does not interfere with diagnostic studies, medical treatment or even later radical surgery if eventually necessary. From their experience with five cases they believe that appendicostomy should be done as soon as the diagnosis of chronic ulcerative colitis is established. They also believe that it is worth a trial even in late cases before resorting to colectomy. The authors are of the opinion that perhaps an important reason for lack of success with the procedure is the fact that appendicostomy has been done with the object of introducing antiseptics or astringents into the colon. This, they are sure, is in error. Its usefulness lies in keeping the intestine clean and free from the irritation of fecal debris and mucopurulent discharge. It provides rest, as near as may be, short of actual diversion of the fecal stream. The technic of appendicostomy (or cecostomy if the appendix has been removed or obliterated by disease) is simple. Care should be taken to avoid interference with circulation by too great traction on or constriction of the meso-appendix. Two of the authors' five patients, after appendicostomy for chronic ulcerative colitis, have been well for more than five years; three have been free from symptoms for sixteen, eight and six months, respectively. Irrigation should be with tap water or physiologic solution of sodium chloride.

*Underlying Causes of Glaucoma: Including Notes on Lines of Enquiry Which Have Been Pursued, with Suggestions as to Future Research in Clinic and Laboratory. P. J. Evans.—p. 745.

Underlying Causes of Glaucoma.—The hypothesis that Evans advances is that: 1. The causes of primary glaucoma are those of capillary and venous stasis, and the condition arises from the changes resulting from such a disturbance of the local circulation. 2. It is held that the symptom complex known as glaucoma includes a number of separate conditions the only features of which in common are those represented by ultimate decompensation of the mechanism provided for the excretion of fluid from within the eye. 3. It is shown that primary glaucoma or glaucoma simplex is the local manifestation of a general disease. It is well established that acute inflammation does not produce more than a fractional rise of tension. Only in the presence of stasis of the circulation in the capillaries and veins does inflammation produce obstruction. The adhesions produced by repeated attacks of inflammation, particularly those between the lens and the posterior surface of the iris, may however restrict the forward movement of the aqueous from the posterior to the anterior chamber, while the formation of a layer of exudate in the layers of and between the fibers of the suspensory ligament of the lens may prevent the exchange of fluids between the vitreous and the aqueous. In such circumstances increased tension may result from mechanical obstruction and a condition of secondary glaucoma is established. The bowing forward of the aqueous behind the iris in cases of ring synechiae is the expression of the greater amount of fluid derived from the increased vascularity of the choroid and ciliary processes, which constitute by far the greater part of the vascular bed. The increased tension in such cases is relieved by broad iridectomy, which breaks the ring of synechiae and reopens the way between the anterior and posterior chambers. In such cases this procedure results in a permanent cure of increased tension, provided further exudates do not block the iridectomy.

*Effect of Heat and Cold on Hemorrhage. S. B. Stoker.—p. 1185.

Rapid Presumptive Test for Weil's Disease.—The test that Brown suggests consists in rocking small quantities of varying dilutions of the patient's serum in the presence of a heavy suspension of *Leptospira icterohaemorrhagiae*. This saline suspension is formalized to a concentration of 0.2 per cent. As *Leptospira* cannot be easily thrown down by means of a centrifuge from the fluid medium in which it is grown, the sedimentation of *Leptospira* from the medium will be facilitated when it is centrifuged by adding to the fluid medium saponin up to a total concentration of 1:1,000. The addition may be made after the culture has been formalized, which makes the procedure free from any risk of infection. Four human strains were compared as regards their agglutinability, both when put up in a water bath for three hours at 56 C. and on the rocking slide. The same serum was used in all cases. The two procedures gave exactly the same titers, but the titers varied according to the strain used. It is thus evident that the strain to be used as an antigen in serologic tests must be highly concentrated and carefully chosen. The dilutions of the serum are made in the depressions of a painter's palette, as in Schüffner's method. They are then mixed with an equal volume of antigen and placed on the slide. This is rocked back and forth for ten minutes, and the result is read by means of a hand lens against a dark background. Numerous serums have been tested by this method and by the macroscopic method after incubation for three hours in a water bath at 56 C. The results have been compared with those obtained with Schüffner's technic and they have been consistently identical, but in every instance Schüffner's

technic has given a titer three times higher than that obtained by either of the other methods. The rocking slide method, given a suitable antigen, will produce a result within fifteen minutes of the receipt of the serum and it is reliable enough to justify the administration of curative serum.

Effect of Heat and Cold on Hemorrhage.—By a series of experiments performed as a preliminary to other work on blood coagulation time, Stoker observed that heat shortened bleeding time but cold greatly prolonged it. It is known that the coagulation time of blood is affected by changes of temperature, but the duration of bleeding time appears to be altered more by the effect of temperature on the tissues than on the blood itself. As bleeding is controlled by plugging the damaged vessels with blood clot, the aim of treatment ought to be directed to this end. Heat is obviously the means to attain this rather than cold, which merely narrows the vessels without accelerating the plugging process. Many men, when questioned, recall that they bleed from a shaving cut much longer on a cold winter day than on a warm summer day.

*Sulfanilamide in Bacillary Dysentery. E. Jones and D. W. Abse.—p. 1259.

Creatinine in Mentally Defective Patients.—Penrose and Pugh estimated in duplicate the creatinine and the creatine in more than 500 early morning specimens of urine from almost 300 male and 100 female mentally defective persons. The patients were kept on ordinary institution diet. The results were expressed as creatinine level and ratio of creatine to creatinine. With use of this simple procedure, the following well established observations were apparent: (1) in muscular dystrophy and in diplegia, creatine excretion was greatly increased at the expense of creatinine, (2) in hemiplegia, by contrast, the results were normal, (3) high creatine was found in hyperthyroidism and (4) in children high creatine and low creatinine were found. The authors believed the method to be qualitatively reliable and they made the following further observations: 1. In cerebellar ataxia and in postencephalitic lethargy creatinine excretion was found to be high. 2. Apart from postencephalitis, no abnormality of creatinine-creatinine excretion was apparent in psychosis with a mental defect. 3. There appeared to be a slight increase in creatine excretion in congenital syphilis. 4. Mongols and epileptic persons gave normal results. 5. Among endocrine dystrophies, results were irregular and in accordance with the nature of each case. It was observed that slight creatinuria is normal on a diet which contains probably less creatine daily than the usual test dose of the drug, even when the estimation is made on an early morning specimen of urine. There is no significant difference between the average creatine excretion of men and women patients. Owing probably to their greater average size and consequently greater muscle bulk, the average creatinine excretion of men is greater than that of women.

Sulfanilamide for Bacillary Dysentery.—As a result of laboratory experiments, Jones and Abse gave sulfanilamide to twenty-one patients suffering from dysentery caused by the bacillus of Flexner. As soon as the clinical diagnosis was established, two 0.5 Gm. tablets were given three times a day for two days. This was followed by one 0.5 Gm. tablet three times a day for two days, making a total of eighteen tablets. All the patients treated had definite fever, toxemia, abdominal pain and tenesmus. The diagnosis of each case was confirmed bacteriologically by the isolation of the bacillus of Flexner, mostly of the W type. Within twenty-four to forty-eight

hours of the first dose of the drug the temperature fell to normal; shortly after this the passage of stools containing blood and mucus ceased, to be followed by the passage of formed stools from which the bacillus of Flexner could not be isolated. An attempt is now being made to investigate its effect on chronic carriers.

Drip Flow Meter for Transfusion. S. R. Gloyne and Phyllis M. Tookey Kerridge.—p. 1267.

Fresh and Stored Placental Blood.—Of the three sources of stored blood (donors, cadavers and placentas) Halbrecht's paper is concerned with the last. Placental blood is easily obtained and easily stored. The pooling of blood for a simple transfusion is an advantage, for it diminishes rather than increases the possibility of a reaction due to incompatibility. In most of his transfusions the author used blood from five or six placentas, and in 220 such transfusions he never saw a severe reaction. Dyspnea was observed in one case and chills in eleven. This incidence of reactions (5 per cent) can be expected also when fresh blood is used. The author discusses the properties of fresh placental blood and the effects of storing. In the summary he stresses that the only chemical change of importance due to storing the blood for a fortnight was glycolysis, increasing from day to day. The chief change in the formed elements of the blood consisted in an almost complete disappearance of the granulocytes after the seventh day. In general the erythrocytes were well preserved; some of them showed from the beginning of the second week changes in form due to shrinking (crab-apple form). The chief physiologic function of the erythrocytes, their power to combine oxygen, was preserved. Slight hemolysis appeared after several days of storing. It was insignificant up to the tenth day and almost never amounted to more than 1 per cent (170 mg. per hundred cubic centimeters) of free hemoglobin in the plasma. On the fifteenth day up to 5 per cent (710 mg. per hundred cubic centimeters) of free hemoglobin was sometimes found in the plasma. In these quantities free hemoglobin does not seem to produce any undesirable effect in the recipient.

Sulfapyridine in Lymphopathia Venereum.—Earle has treated twenty-four cases of lymphopathia venereum (venereal lymphogranuloma) with sulfapyridine. The results have been uniformly successful, as is demonstrated by the twelve clinical histories he reports. This series includes most of the types of venereal lymphogranuloma except gross elephantiasis of the vulva and rectal stricture in the male. The optimal therapeutic stage is during the early days of the inguinal adenitis. When fistulas have formed, treatment is prolonged. In the female the best results are obtained during the stage of adenitis, but even in later stages treatment is of value. In two cases rectal stricture was favorably influenced. A feature of treatment of lymphopathia venereum with sulfapyridine which is worthy of trial is the sterilization of female carriers. These often have no obvious clinical signs but invariably show a positive Frei reaction. The treatment of inmates of brothels in tropical ports, who probably form an important focus for the maintenance of lymphopathia venereum, might be of value in reducing the incidence of infection in the male. The most satisfactory dosage of sulfapyridine in this condition appears to be five or six 0.5 Gm. tablets daily for five days. Depending on the response, additional five day courses can be given at intervals of three or four days.

*Diagnosis of Infectious Mononucleosis: Value of Serologic Reactions. R. Demanche.—p. 1614.

Diagnosis of Infectious Mononucleosis.—Demanche reports his experiences with the serologic test (agglutination reaction) devised by Davidsohn and somewhat modified by the author in 239 cases of true and false infectious mononucleosis. One hundred and forty-seven cases, including angina, acute and myeloid leukemia, Hodgkin's disease, lymphadenia, leukemoid manifestations and other abnormalities could be eliminated as simulating the clinical picture. In nearly all these cases the agglutination titer was low, three fourths not exceeding 1:28. In fifty-seven cases presenting the classic picture the agglutination test was positive. White blood cells varied between 10,000 and 20,000 (on one occasion as high as 28,800). The mononuclear cell count ranged from 50 to 80 per cent. All fifty-seven cases, with the exception of eight, showed a titer evaluation ascending from 1:224. The variations in agglutination did not seem to agree either with the intensity of the disease or with that of the leukocytic reaction but were due in part to the time when the tests were made, that is between the eighth and the fifteenth day, rarely earlier. The disease could be identified even when a low agglutination titer was present by the complete absorption by the beef erythrocytes. The author found that serologic modifications were not discoverable at the beginning of the disease but were always present by the eighth day and had reached their acme between the eighth and the fifteenth day. The agglutinating power of the serum diminished rapidly and fell from more than 1:14,000 and 1:28,000 to 1:112 within the space of two months, simultaneously with the reestablishment of the leukocytic equilibrium. The termination of the reaction was signaled by the disappearance of the typical agglutinations and the return of Forssmann's antibodies. The author found the serologic test clearly and constantly positive in all cases of proved infectious mononucleosis except two doubtful ones.

Malignant Development of Royal Tumor in Familial Recklinghausen's Disease. R. Huguenin, S. Burgi and J. Barbet.—p. 287.

Muscular Hypertrophy and Hypothyroidism.—Darré and his associates distinguish three different types of generalized muscular hypertrophy in nurslings which they designate by the names of authors who have described them: (1) the syndrome of Debré-Semelaigne, (2) the syndrome of Cornelia de Lange and (3) Thomsen's disease of nurslings. They report the history of an infant with generalized muscular hypertrophy, which involved even the diaphragmatic, gastric and cardiac muscles. The muscular hypertrophy did not show clinical, mechanical or electrical signs of myotonia; it was without concomitant neurologic signs and was definitely congenital but devoid of hereditary or familial character. On the other hand, the infant presented attributes of congenital myxedema. Thyroid was given, at first without effect; later it became effective in that the muscular hypertrophy as well as the signs of hypothyroidism disappeared. The authors also discuss the three aforementioned types of generalized muscular hypertrophy of nurslings. The syndrome of Debré-Semelaigne is characterized in nurslings by the association of generalized muscular hypertrophy, muscular rigidity, retardation in the intellectual development and a myxedematous syndrome. The amelioration of the thyroid deficiency by organotherapy is followed by improvement in the other symptoms. In nurslings with the syndrome of Cornelia de Lange the following triad concurs: generalized muscular hypertrophy, extrapyramidal hypertonia and mental deficiency. The syndrome of Cornelia de Lange has two symptoms (general muscular hypertrophy and mental deficiency) in common with the syndrome of Debré-Semelaigne; the third symptom, the extrapyramidal disturbance, places it at least

provisionally in a special class. Nevertheless the authors think that intense and prolonged treatment with thyroid is advisable even if the examination of the child fails to disclose signs of hypothyroidism. Regarding the syndrome of Débré-Semelaigne, they say that it is already represented by an appreciable number of cases but that its definition should be more precise and that the term congenital myxedema should be replaced by thyroid insufficiency.

Polyradiculoneuritis Guillain-Barré: Case. Anita Saurer.—p. 1222.
Paroxysmal Attacks of Coughing in Adults as Masked Form of Pertussis. M. E. Bircher.—p. 1226.

Hypophysial Tuberculosis as Cause of Death.—Berblinger reports the case of a woman aged 52 who injured the back of her head in a fall. Convulsions and coma set in and she died. The necropsy disclosed extensive atrophy of the entire hypophysis, the weight of which had shrunk to 0.31 Gm., leaving no distinguishable demarcation between the two lobes. Epithelioid cell tubercles with typical giant cells and caseation were found in what remained of the gland. Likewise a bilateral atrophy of the adrenal cortex, especially in the zona fasciculata, was discovered. In the lower lobe of the left lung were subpleural calcifications and small clarified cavities in the apex of the lung with cicatrices in both apexes and healed endocarditis in the aortic valves. There was almost complete absence of pubic and axillary hair. No external signs of occipital contusions were found nor did microscopic inspection of the brain indicate recent softening, scars or hemorrhages. Authentic proof of hypophysial tuberculosis, the author states, can be furnished only by necropsy. In the absence of this the real cause of a patient's death may escape notice. This may account for the fact that only twenty-one cases have been reported.

- *Frequency and Significance of Tuberculosis in Rheumatic Fever. M. Pellegrini.—p. 505.
Clinical and Roentgen Aspects of Hypertrophic Gastritis. P. C. Taliani and E. Zanetti.—p. 531.

Tuberculosis in Rheumatic Fever.—Pellegrini discusses the frequency and etiologic relations of tuberculosis and rheumatic fever. He made a clinical study of seventy cases of typical rheumatic fever without any symptoms of tuberculosis (either pulmonary or extrapulmonary). The patients were observed during the first acute attack or during a recurrence of the disease. The author found that in thirty-seven cases in the group the repeated x-ray examination of the thorax showed the presence of pleuropulmonary tuberculosis either in evolution or healed. The Mantoux test gave positive results (three plus) in fifteen cases in which pleuropulmonary tuberculosis in evolution was present, in seventeen of twenty-two cases in which there were healed pleuropulmonary tuberculous lesions and in twenty-three of thirty-three cases in which x-ray signs of pleuropulmonary tuberculosis were absent. The author concludes that tuberculosis is frequent in rheumatic fever as an associated infection. The tubercle bacillus is not concerned in the development of rheumatic fever. Mixed tuberculous and rheumatic forms become apparent by predominant (or exclusive) symptoms of either infection. Rheumatic fever has a stimulating action on tuberculous allergy. The stimulation in certain cases results in the development of hyperergic reactions.

- *Roentgen Treatment of Hyperfunction of Thymus (Pende's Syndrome). S. Gualeo.—p. 1659.

Roentgen Treatment in Hyperfunction of Thymus.—Gualeo observed and followed the behavior of the crisis of the blood and of the basal metabolism in twenty-five adolescents who were suffering from adiposity, genital dystrophy and retarded somatic and mental development from hyperfunction of the thymus (the so-called Pende syndrome). The observations were made before and after administration of roentgen irradiations on the thymus region by Pende's technic, which consists in irradiation of 100 roentgens through a filter of 3 mm. of

aluminum and 0.5 mm. of copper on the thymus region. The irradiations are given every other day, up to a total number of four for each cycle, which is followed by a period of rest for twenty days during which time the patient has no treatment. The complete treatment consists of three cycles of irradiations. The author found that in all cases the somatic genital and mental disturbances are controlled by the treatment. He also found that before administration of the treatment total absolute and relative lymphomonocytosis and neutropenia and moderate disturbances of the basal metabolism exist which are controlled by the treatment.

*Toxicology, Clinical Aspects and Pathologic Anatomy of Nickel Carbonyl Poisoning. O. Bayer.—p. 592.

Nickel Carbonyl Poisoning.—Bayer says that his clinical experience with carbonyl poisoning corresponds with that of Brandes in America and that reported from a refinery in England. He found that in the majority of cases the symptoms disappear in from eight to fourteen days. The pulmonary symptoms increase and lead to a secondary involvement of the heart and the circulation only in the severe cases, and death follows under the signs of cardiac failure. The necropsy is given in two cases. The author concludes that nickel carbonyl acts as an inhalation toxin on the large surface of the respiratory epithelium and produces the aspects of a toxic pneumonia, with simultaneous involvement of all parts of the lung. It is difficult to explain to what extent the frequent cerebral hemorrhages are caused by absorbed nickel carbonyl or to what extent they may be asphyxiation hemorrhages. The pulmonary symptoms in the form of dyspnea, irritative cough and pains along the costal arches dominate the clinical picture. The pathologic anatomic picture is characterized by a peculiar coagulation process in both lungs. Microscopic examination reveals that the pulmonary alveoli are filled with a fibrin precipitate, whereas cellular blood elements are almost completely missing. In the treatment the author obtained favorable results with the intravenous administration of large quantities of dextrose solution and by medication with calcium, strophanthin and circulatory stimulants of the camphor series.

Granulocytopenia with Vitamin C.—Kalk reports the successful use of ascorbic acid in six cases presenting different disease backgrounds but all characterized by granulocytic deficiency in the leukocytic blood picture. The age of the patients was between 21 and 56 years. The following disease conditions were represented: bilateral glandular swellings of the neck with intrabuccal inflammations and refractory digital lesions of an occupational nature, pyrexia and coma; rheumatism of thirty-five years' standing with icterus, lesions in the scrotum and perineum; dermatitis resembling scarlatina with diarrheal discharges, icterus and stupefaction; chronic polyarthritides rheumatica and signs of myocarditis and endocarditis; bronchopneumonia and thrombosis of the right leg; and lumbago, pains in the upper arms and legs, angina and necrosis at the right palatine arch. The analysis of the white corpuscular blood content disclosed a leukocytic count as low as 2,600 and 3,000, with granulocytopenia at the zero point and lymphocytosis at an elevation of 75 and 92 per cent. Treatment of the patients consisted of intravenous doses of vitamin C varying from 50 mg. to 5 Gm. According to the author, vitamin C therapy, by improving the leukocytic picture, achieved remarkable results and practically saved the life of three patients, besides healing the digital lesions and the inveterate rheumatism. Vitamin C was observed to be capable of causing prompt reactions. In one case reduction of dosage, by administration on alternate days, at once affected the patient unfavorably, whereas restoration to a daily schedule promptly stimulated favorable effects. In spite of the absence of the considerable diminution of granulocytes in the blood stream, the

author classifies his cases among those with a more favorable prognosis because of their relatively high leukocytic count. He regards granulocytopenia as due to delayed maturation or impeded release in the bone marrow. Vitamin C, in his opinion, is prophylactically indicated whenever a disease presents a decrease in leukocytes and granulocytes. He also records the inefficacy of vitamin C therapy in eight cases of myelocytic leukemia, though doses were as high as 1 Gm.

Dilatation of Biliary Passages. M. Graubau.—p. 614.

Hormonal Diagnosis of Testicular Tumors.—According to Ehrhardt and Breitenbach, an analysis of the urine for the presence of hormones is indicated in every case of testicular disease. A repeatedly positive luteinizing reaction in the urine is diagnostic of a malignant growth of the testis. Diagnostic conclusions are not justified on the basis of a single negative luteinizing reaction. A negative luteinizing reaction and a positive follicle stimulating reaction call for further urinalyses. A repeatedly positive follicle stimulating reaction in the absence of a positive luteinizing reaction is suggestive of a malignant condition of the testis but not decisive. No conclusions are justified on the basis of an occasional positive follicle stimulating reaction. A malignant tumor may be present even though both reactions are negative. Here one must depend entirely on the clinical characteristics of the tumor. A favorable prognosis is indicated when a hitherto positive luteinizing reaction is repeatedly negative after the operations for the removal of the involved testis. The authors suggest that the urine be examined for hormone in every case of gynecomastia because of its frequent association with malignant conditions of the testes. Such examinations would result in recognizing early cases of malignant tumors of the testis. An extragenital chorionepithelioma may give rise to a positive luteinizing reaction in the urine. The authors have reviewed the literature and found that the luteinizing reaction proved positive in the following types of testicular tumor: seminoma, chorionepithelioma, teratoid, carcinoma, dysgerminoma, embryoma and adenocarcinoma. Of the nine cases reported by them, three gave a positive luteinizing reaction. The remaining six gave a positive follicle stimulating and a negative luteinizing reaction. Both reactions were negative in a group of nine cases with inflammatory disease of the epididymis.

Paget's Deforming Osteodystrophy.—According to Brunner, there were twenty-six cases of Paget's osteodystrophy observed in the Clairmont clinic (Zurich) in the last ten years. The majority of the patients were admitted to the clinic because of complications. In 70 per cent the diagnosis was arrived at from x-ray examination. Earliest symptoms were noted between the ages of 31 and 65, on the average at 50 years. Prodromal symptoms lasted as a rule about six years before they were recognized by a physician. The relationship of the incidence in men and in women was as 19:17. Familial incidence was observed in only one instance. Seventy per cent of the patients presented rheumatic complaints, 20 per cent pathologic fractures, while 10 per cent were symptom free. Spontaneous fractures were relatively rare and occurred only in cases exhibiting high grade osteoporosis. There were thirteen fractures of the tibia, nine of the femur and pelvis, seven of the humerus, six of the vertebrae, five of the skull, three of the scapula and the fibula, two of the sternum and rib, one of the tarsal bone and one of a phalanx. They have not observed any cases of circumscribed osteoporosis of the skull. All the traumatic fractures, even those in the advanced age, healed satisfactorily. Bony deformities were caused less frequently by the fractures. They were more frequently due to unilateral increase in the growth and to muscle pull. The roentgenologic observations were as a rule typical; genuine cysts were not observed. Roentgenologically the cases had to be differentiated from Recklinghausen's disease, osteomalacia, osteoplastic carcinomatous metastasis and primary latent

osteomyelitis. The joints did not appear to be involved. Nervous disturbances as the result of bony encroachment at the exits of the nerves or as the result of pressure on the brain were observed relatively seldom. With a single exception the phosphatase blood content was abnormally increased, corresponding to the severity of the disease. The blood calcium level was never abnormally increased and in one half of the cases was found to be at the lower level of the normal. A mild hyperphosphatemia was frequently observed. There was no increase in the excretion of calcium and potassium in the urine. Nephrolithiasis was never observed. The majority of the cases presented neither hereditary nor constitutional etiologic factors. Trauma as a rule exerted an unfavorable influence. The only endocrinologic disturbances were those of a fairly frequently observed increase in basal metabolic rate, suggesting a functional disturbance of the thyroid gland.

Differentiation of Gout and Tuberculosis.—Kienböck says that in general practice chronic articular disturbances are usually diagnosed as one of the following disorders: chronic articular rheumatism, arthritis deformans or gout. He thinks that x-ray examination should be employed more frequently. He describes five cases of painful nodular disorders of the joints of fingers or toes, some of which presented considerable difficulties in the diagnosis especially in the differentiation between true gout and tuberculosis. He admits that the clinical and roentgenologic aspects of these two disorders are similar in some respects. Both are characterized by pains, articular swellings, redness of the skin and formation of fistulas; x-ray examination occasionally reveals cystic destruction of the bone without or almost without increased density of the bone and with small sequestrs and roundish masses. However, there are also some differences: uratic gout is characterized clinically by the well known attacks of pain and by the fact that the fistulas secrete whitish masses, uric acid, which are rarely mixed with pus. The x-ray examination in these cases reveals in the destroyed part of the bone little or no densification; the nodules appear in most cases entirely "light," in rare cases cloudy, secondarily calcified and ossified. Tuberculosis, on the other hand, is characterized by moderate pains; there are no real attacks. The fistulas secrete caseous masses, small sequestrs and pus; some of these fistulas are caseated abscesses. The examination with x-rays discloses densification of the bones, and the attached masses are usually cloudy and occasionally contain small sequestrs. If made with care, x-ray examination usually permits a correct diagnosis. To be sure, errors do occur. One of the cases which the author identified as gout had previously been diagnosed as chondroma of the bone and again as osteitis fibrosa cystica. In some cases even x-ray examination will not permit a differentiation between gout and tuberculosis, and only an operation will clarify the case. It will reveal either uric acid or tuberculous pus, occasionally with bacilli. Examinations of the urine and of the blood are of value if they produce positive results, but they are of no significance if they produce negative results.

Interruption of Pregnancy and Sterilization on Basis of Cardiac Indications. F. Lange.—p. 1557.

Azosulfamide in Cholangitis.—Mancke and his associates show that bacteriocholia must be strictly differentiated from biliary infection. Studies in nearly 1,000 cases revealed that bacteria are present in many cases in which infection is absent. After reviewing the bacteriologic aspects of cholangitis and the customary therapeutic methods, they point out that in recent years chemotherapy has assumed great importance from the

standpoint of choleresis and of disinfection. As regards choleresis, the parenteral administration of the pure bile acids signified a considerable advance. However, as regards the possibilities of disinfection of the biliary tract the chemotherapeutic measures still lack a good foundation. Combinations of bile acids with disinfecting agents have been recommended for disinfection, but little is known regarding their elimination and their bactericidal effect. Since derivatives of sulfanilamide have been used in infections with cocci and with organisms of the coli group, and since such infections are often found in the biliary tract, the authors decided to make experimental and clinical studies on the use of azosulfamide. Experiments on dogs with biliary fistulas concerned its elimination. The clinical observations were made on extensive material of a clinic in Leipzig, where azosulfamide has been used in treatment of biliary disorder the last eighteen months. It was administered orally in a dosage of three times 0.6 Gm., usually in combination with hydrochloric acid-pepsin or intramuscularly (from 5 to 10 cc. of a 2.5 per cent solution); or, to intensify the action, these two forms of application were combined for the duration of six days. In combination with the customary dietetic and physical therapy, medication with azosulfamide produced good therapeutic results. In some cases cure was rapid with a critical defervescence. The authors gained the impression that azosulfamide is particularly valuable in cases of inflammatory diseases of the biliary tract which are accompanied by acute symptoms, such as high fever, colic-like pains and more or less pronounced jaundice. The inflammatory symptoms react especially well to azosulfamide. Moreover, the general condition improves rapidly in cases in which the cholangitis has a septic character and is accompanied by chills and malaise. On the other hand, in chronic infections of the biliary tract, azosulfamide produced no improvement.

Treatment of Tuberculous Empyema with Diluted Solution of Sodium Hypochlorite. A. V. Pakhomov, I. A. Shakleya and E. L. Papsheva.—p. 23.

Complications Following Thoracoplasty.—According to Kapushchevskyy and Kiselev, the most frequent complications after a thoracoplasty are those involving the pulmonary tissue. They present themselves, as a rule, either as asymptomatic atelectases or atelectatic pneumonias. The authors consider the latter an allergic inflammatory phenomenon caused by the tuberculous virus. Atelectasis, when accompanied by considerable exudate, may resemble a massive pneumopleuritis. The satisfactory condition of the patient, absence of displacement of the heart to the opposite side and rapid absorption of the exudate speak for atelectasis. Postoperative pneumonias resulting from infection of the pulmonary tissues with virulent organisms and not associated with atelectasis is a grave complication. Complications involving the opposite side are rare. Cardiovascular decompensation has not been frequently observed.

Hepatic Calculi. B. A. Benavente.—p. 5738.

Chemotherapy of Gonorrhea in the Male.—Polano designates as chemotherapy of gonorrhea the oral or parenteral administration of the derivatives of sulfanilamide. There is no agreement as to which of the different preparations is the most effective in gonorrhea. Of the basis of his experiences and data found in the literature, he concludes that sulfapyridine produces at present the best results. Among fifty male patients who had been infected from three days to several months previous to the onset of the chemotherapy, forty-six were cured by the oral administration of sulfapyridine alone. During the first three days the patients were given daily six tablets of

0.5 Gm. each, then for three days four tablets daily, and finally for three days two tablets daily. In the majority of cases the criterion of cure was that ten provocations be successfully sustained, which consisted of four instillations of 1 per cent solution of silver nitrate, of two prostatic massages and of four bougienages.

*Pathogenesis in Venous Thrombosis and Mechanical Prophylaxis. R. Frykholm.—p. 3534.

Pathogenesis of Venous Thrombosis.—Frykholm states that his study of necropsy material comprising twenty-four cases with pulmonary embolism show four sources of beginning thrombosis: the musculature of the calf of the leg, the adductor musculature, the plantar region and the pelvic veins. An ascending thrombus seems to pass from these regions in the direction of the blood stream, while retrograde thrombosing is rare. Early clinical diagnosis of thrombosis requires a thorough examination of these four regions. Veins with varicose distention for a greater extent and thin walls partly collapse during confinement in bed, whereupon intima lies against intima. This occurs particularly in the musculature of the calf of the leg and the adductor muscles, which take the least part in the active movements performed in bed and through which minimal amounts of blood pass. In addition there is mechanical pressure. The veins of the soles of the feet and the pelvis can also be assumed partly to collapse under certain conditions. Normal metabolism of the intima depends on contact with the circulating blood. When two intima layers are pressed against each other, a disturbance in the nutrition of the endothelium can easily occur. This injury of the blood vessel endothelium is considered an important primary condition in the origin of thrombosis. Substances given off by the damaged endothelium and by the thrombus promote coagulation, and the thrombus grows in the direction of the blood stream. In stagnant blood a red thrombus develops, in quickly flowing blood a white thrombus. In mechanical prophylaxis against thrombosis of the lower limbs the author believes that the veins of the lower extremities must, at least periodically, be sufficiently distended with blood and the circulation in the threatened region be sufficiently rapid. Consequently he advocates raising the head of the bed so high that the patient has the feeling of slipping down and is forced to active exercise of the muscles of the calf of the leg and the adductor group.

*Calcinosis Circumscripta: Report of Case with Clinical and Etiologic Considerations. E. Westerlund.—p. 3563.

*Insulin Compared with Histamine as Stimulant for Gastric Secretion. P. Horstmann.—p. 3566.

Calcinosis Circumscripta.—Westerlund reports a case of calcinosis circumscripta in a woman aged 54 with simultaneous Raynaud's disease. The frequent occurrence of the condition in cases of scleroderma and Raynaud's disease is emphasized. The increased calcium content in scleroderma in connection with chronic traumas, when this combination occurs, is assumed to be the cause of the manifestation of calcinosis circumscripta. The question remains, the author says, whether similar conditions prevail in the uncomplicated cases and those complicated with Raynaud's disease.

Insulin Compared with Histamine as Stimulant for Gastric Secretion.—Horstmann tested these two agents in six cases of neurologic or psychiatric disorders, one with normochylia, five with achylia. Fractionate alcohol test meals were given. In all cases insulin was more effective than histamine, and insulin caused secretion of gastric juice where the histamine had no effect. The value of insulin in anxious, depressed patients without appetite is stressed.

The Patient and the Art of Living

AN APPROACH TO PSYCHOSOMATIC MEDICINE

WILLIAM H. BARROW, M.D.

SAN DIEGO, CALIF.

The purpose of these lectures is to explore the realm of the so-called affective disorders, especially those states of mental conflict and maladjustment with predominantly physical complaints. I hope we may stimulate in you who are about to go out as practitioners in medicine an interest in this generally neglected and oftentimes unrecognized field.

A London physician¹ discussing the curricula of medical students said "What they really need to know is the Art of Living. And how is that to be taught?" I have often felt that these patients would never have needed help, would never have been ill, if they had had an ample and wholesome background, a philosophy of life, an established code of conduct to buffer the strains of ordinary life.

In any type of practice one is constantly seeing this class of patient, but for the internist it constitutes a large percentage of his practice. This may be due partly to the fact that having made the rounds of the general practitioners and of specialists who have not looked beyond their limited fields such patients finally come in for a complete diagnostic work-up. In a practice limited to internal medicine, psychoneurosis as a primary or secondary diagnosis may be found to outnumber all others in frequency except the cardiovascular diseases and the endocrine disorders. It occurs as frequently as gastrointestinal disturbances. It is considerably more common than the pneumonias or blood dyscrasias.

This is a situation that often stuns and baffles the young practitioner making his first contact with private practice. At school and even in the teaching hospital he has mechanized his study of the patient. Physiologically, anatomically and even pathologically he has been dealing with a fairly definite science. In the study of patients, routine questions are asked regarding

subjective symptoms, physical signs are elicited and laboratory investigations galore are made; then the results are tabulated and correlated much as an engineer would work with his slide rule, and a definite diagnosis is established. Treatment is almost as routine, and one has a glow of satisfaction over one's workmanlike technique. When the physical and laboratory observations fail to fit the subjective symptoms the patient is dismissed with a blithe "Well, we can find nothing wrong with you" and the diagnosis is filed as "No disease found." But there is something wrong, there is something wrong or these people would not be appealing for help, and the private practitioner cannot so blithely dismiss the sufferer who has come to him for help.

THE PROPER APPROACH

Psychosomatic disease may be defined as a condition in which the chief complaint is usually physical, the subjective symptoms are usually out of all proportion to the physical findings, and there is always an underlying and often obscure mental or psychic disorder based on a constitutional inadequacy and on some environmental or circumstantial conflict.

In organic disease the symptoms are clearcut and are apt to be minimized by the patient. In the affective disorders the complaints seem to spread out like the waves on a pool of water into which a stone has been thrown, where though the primary disturbance is really slight the turmoil of the waters is great. Nevertheless these somatic manifestations are due to some real functional or mild organic disorder. They are not imaginary. True, the patient's threshold to pain and discomfort is lowered or he compensates poorly for his disability. But where there is a physical complaint there is an underlying physical defect that needs attention. Incidentally the patient who is having neurogenic but nevertheless very real abdominal distress may rightly be much dissatisfied with the medical opinion that because the gastrointestinal

From the Department of Medicine, University of Southern California School of Medicine. Lectures to the Medical Students under a fund established by Mrs. Clark M. Cavenee.

1. Banister, Harry: *Psychology and Health*, New York, Macmillan Company, 1935, p. vii.

series and other investigations are negative there is nothing wrong with him. In fact the somatic complaints offer an opportunity to the physician to give the patient relief and thereby win his confidence and trust much more effectively than psychotherapy alone could ever do.

It is unfortunate that in the mind of the layman there is a stigma attached to mental disorders, but he does resent being told that his trouble is all "nerves" and resents being sent to a physician who treats only "nerves." The neurasthenic patient seldom consults his doctor for nervousness but rather for indigestion or palpitation of the heart or for some other physical ailment, and he is more interested in the relief of these symptoms than in diagnosis. A patient who had had severe headaches all her life once told me that because there was nothing organically wrong with her she had been referred to a psychiatrist, that she had been psychoanalyzed and had been told that she was a Peter Pan type of individual, that she would have been all right if she could have remained a child and that it was a mistake for her to have assumed the strain and obligations of married life and motherhood. "Well," she said, "That may be true, but what am I going to do about it now? I still have headaches."

I do not wish to minimize the help that may be rendered by psychiatric consultation and advice but what is needed in the attending physician is not a highly specialized knowledge of psychiatry or of any other of the specialties but rather a breadth of medical vision and skill that will enable him to make the patient comfortable. In addition he must have a large fund of patience and compassion and common sense so that he can establish contact with the patient and win his confidence. The proper approach to these cases might, therefore, be said to be one-third psychiatric, one-third physical and one-third compassionate guidance in the Art of Living.

WHY THEY SEEK RELIEF

With somatic complaints looming large in the patient's consciousness and with the treatment of these physical ailments so important, what then are the disorders for which the psychoneurotic person seeks relief? By far the largest number (37 per cent of a series of 250 cases studied) complain primarily of gastrointestinal disturbances. Although positive and often severe, the symptoms usually fail to fit any established pattern. Quite typical are postprandial bloating and distention, intestinal gas with eructation and flatus, migratory and ill defined pains, constipation often alternating with diarrhea, and most characteristic of all a real or alleged idiosyncrasy for many common foods. Gastrointestinal roentgenograms in these cases are negative except for evidence sometimes of disorders of motility and peristalsis,

and gastric analysis reveals no disturbances of gastric acidity or rate of secretion. This is important to remember in treatment where belladonna and its derivatives are usually indicated but where alkalis so commonly given for nervous indigestion are not. In fact, the giving of alkalis may aggravate an already existing alkalosis of nervous origin.

Second in order of frequency are cardiovascular symptoms (a primary complaint in 17 per cent of the series). In these cases there is palpitation, irregularity due to premature contractions, and precordial pain usually described as either a constant mild ache or as a sharp sticking or pricking sensation not related to exertion. This pain is utterly unlike the pain of coronary disease with its squeezing substernal oppression or its severe knifelike stabbing pain through the precordium or radiating to the arm. Patients with neurogenic heart disease always claim to be short of breath on exertion, but this is obviously not a true dyspnea. Not infrequently this type of patient has been told by some casual physician that he or she had a "weak heart" and has taken digitalis. This is tragic, because the patient becomes heart conscious and a cardiac neurasthenic. It is so much easier to convince patients that there is something wrong than that there is nothing wrong. Examination of these individuals often shows poor reaction of pulse and blood pressure to change of position and exercise but essentially negative electrocardiographic manifestations. The trouble is obviously due to sympathetic nervous system imbalance and calls for sedation, regular graduated exercise, and reassurance in large doses.

The psychoneurotic patient seldom limits his symptoms to one bodily system. In fact it is quite characteristic that in giving his history the psychoneurotic individual seems to be a jangling mess of dysfunctioning organs. Questions directed at the nose and throat, the eyes and ears, the cardiovascular system, the lungs, the gastrointestinal system, the genito-urinary system and so on throughout all monotonously reveal some complaint.

The general complaint of malaise and fatigability is most common (a primary complaint in 14 per cent of the cases). It is characteristic that this is malaise rather than fatigability. The patient is tired when he wakes up, tired and ambitionless during the day, and tired when he goes to bed at night. Yet when called on for something that has to be done he somehow forgets himself and musters the strength to do it. This symptom is a source of worry to the examining physician and of expense to the patient because of its suggestiveness in differential diagnosis. One must consider and rule out anemia, hypothyroidism, hidden cancer, masked renal disease with toxic symptoms, tox-

emia from hidden foci of infection, myasthenia gravis, hypoglycemia, early Addison's disease, tuberculosis and, of course, syphilis in one of its bizarre manifestations. Malaise is a trouble making symptom because it is essentially mental and not physical in origin. It is a protective mechanism against the demands of the World. But it can be labeled neurogenic in origin only by a system of elimination. In its specific treatment mild sedation often accomplishes more than stimulation, although a morning dose of amphetamine sulfate often seems indicated.

"Aches and pains" was the primary complaint in 10 per cent of the cases as well as a secondary complaint in most of the others. This may take the form of a general myositis or of definite backache, headache or neuritis. The symptoms are often so vague that one wonders if they are real, but so persistent that one is forced to conclude that they are due to toxemia, possibly gastrointestinal in origin or due to neurovascular disturbances. Massage and physical therapy often bring welcome relief in these cases. This is the type of symptom which is apt to make the patient the slave of the medicine bottle or of many bottles, especially if the hurried and distraught physician reaches for his prescription pad at the recital of each new ache. Better perhaps to mix a little tolerance for discomfort with some of the medication.

MENOPAUSAL SYMPTOMS

The next group (7 per cent of the series) is of considerable interest and more gratifying to work with because specific treatment yields such encouraging results. This is the group with menopausal symptoms. The symptom complex is one that is almost classic in its uniformity. There is malaise and yet restlessness. There is an occipitocervical neuralgic "headache." There are vasomotor disturbances manifesting themselves as "hot flashes" and excessive perspiration—a perspiration started by excitement rather than by exertion. There is often palpitation of the heart and sometimes irregularities due to extrasystoles. Intestinal indigestion is not an uncommon complaint. Changes in the character and regularity of the menses is usual. And finally there is arthritis of the menopause, probably secondary to vasomotor dysfunction. This arthritis typically affects first the knees and the proximal phalangeal joints. The patient complains of some pain and stiffness in going up stairs and of stiffness and swelling of the fingers. The swelling, when it occurs, is due to periarticular tissue edema. X-ray examination, which is at first entirely negative, will later typically show degeneration of the synovial membrane and of the end of the bones, and hypertrophic lipping of the joint margins. These symptoms are presumably due to endocrine dysfunction and the treatment is specific—the

administration of estrogenic substance, preferably parenterally, and of thyroid if it is indicated or tolerated. Treatment of the condition is otherwise symptomatic such as mild sedation, atropine for the hyperhidrosis, and dietary restriction for the indigestion. The psychoneurotic state so often accompanying the menopause is not to my mind an endocrine born disorder. It is undoubtedly caused or aggravated by the somatic complaints; but of its real basis I shall treat later.

It is not uncommon for otolaryngologists to see the psychoneurotic first (5 per cent of this series referred the trouble primarily to the nose and throat). The complaint is usually of a soreness or aching in the throat or of nasal symptoms in spite of a grossly negative physical examination. In the differential diagnosis a masked infection with Vincent's spirochete must be kept in mind, and there are cases of peridental Vincent's invasion without the usual ulceromembranous lesion, when a sore and aching throat normal in appearance is the only sign.² However there are many cases for which there seems to be no physical basis and which must be labeled as purely neurogenic in origin.

There is very definitely an arthritis that is typical of the psychoneurotic state. It is hypertrophic in type and although chronic in its course is subject to more variation than the usual hypertrophic arthritis of old age. The treatment other than that aimed at the psychic background is as it would be for the other arthritides. Arthritis was the primary complaint in 4 per cent of our series.

Strangely enough, genito-urinary complaints seem rare as the outstanding symptom (3 per cent). Even neuroses based on sexual maladjustment manifest themselves first elsewhere in the body. Cutaneous lesions, especially pruritus, occur occasionally, as does low grade fever. The neurogenic fever is a constant source of worry to the attending physician because of the fact that, although every possible cause of fever has been investigated and discarded, one always fears that something has been overlooked. However, in spite of this apprehension and of a desire to follow the daily temperature curve as a stock broker might follow the ticker tape, it is usually advisable to have the patient throw away his thermometer and forget his fever.

TAKING THE HISTORY

In the taking of the history, the recital of the physical ailments usually rushes on in an unending stream, the patient often somewhat petulantly brushing aside any attempt on the part of the examiner to direct his recital into any well ordered plan or description of any recognized symptom complex. Yet of the psychic factors

2. Barrow, W. H.: Systemic Reaction to Oral Fusospirochetosis Without Local Lesions. *Ann. Int. Med.* 12: 508 (Oct.) 1938.

he usually says nothing until subtly pressed for information. How, therefore, is this so important information to be elicited and when? It is essential that the past and present life of the patient be reconstructed. Leading questions are asked and hints of conflict or maladjustment are followed up as tangents from the main line of questioning as they arise. "Where did you live as a child? What did your father do? Were you comfortably provided for? Was your home life happy? Did you enjoy school?" Answers to these personal and pertinent questions elicited in a sympathetic and tactful way will often reveal a faulty background which partially explains the present mental state. "What did you do after you left school? Did you enjoy your work?" The wistful eagerness with which this last question is often answered in the affirmative is illuminating and pathetic. "Where did you meet your present husband? What is he like and what does he do? What does your immediate family consist of, that is, who constitute your household?" In-laws who may be the unconsciously irritating factors often reveal themselves here. "Do you do your own housework? What time do you get up in the morning? What do you do after breakfast—and after lunch? Do you find time for outside interests? Do you take any exercise? Have you any real hobbies?"

BALANCING THE BOOKS

After delving into the lives of patients, one is impressed with how poorly most individuals plan their lives for pleasure, for the use of their leisure hours. Yet when we balance our books at the end of life the two questions that it would seem must sum things up are "What have you accomplished and more important still how much fun have you had—how much enjoyment?" Often then in getting an answer to the questions "What do you do with your leisure time and what are your hobbies" one runs on a gold mine of information—thwarted desires, inhibitions, aimless and restless efforts at escape, or stolid resignation and lack of interest—the depth of the patient's background. In fact, I often think that from the answer to this question I can then and there make a prognosis. I am given a hint as to quality and quantity of the material with which I have to work. And so the patient's portrait begins to unfold. "What do you do with yourself evenings? Do you have many friends? Do you enjoy seeing them? Do you get out to parties and dances and other forms of entertainment as much as you would like to?" Here sometimes for the first time one uncovers evidence of marital incompatibility or of maladjustment to marriage. The husband comes home tired and wants to read the paper and go to bed. The wife, anxious for escape from her oppressive "four walls," would like to do otherwise—or perhaps both husband and

wife, chafing at the bit, are tied down by children who cannot be left alone.

Detailed questioning with regard to sexual relationships are, of course, of great importance and fortunately, as the result of public education in these matters, such questions are not only not resented but are welcomed as an opportunity to discuss problems the patient has long wanted to discuss or at least to satisfy some natural curiosity. And again as tangents from this angle one often obtains an illuminating glimpse of some unsuspected character complex. I do not, however, believe that from the point of view of practical psychology most or even many mental problems can be laid at the door of sexual repression.

In spite of or perhaps because of the intimate nature of these questions, it seems advisable to get this information at the time of the first visit. The patient is then usually in a mood to tell his whole story, his feelings toward the physician are purely impersonal, and there is therefore apt to be less reticence than there would be later on; and perhaps most important of all at this time the patient has not yet centered his attention on the treatment and progress of his physical ailments.

This type of questioning is not a very searching psychiatric examination. In fact it is not in one sense psychiatric at all. It merely constitutes an effort on the part of the examiner to reconstruct the patient's background and environment, to get a true picture of him as a human being and not as merely a physiologic and pathologic machine. Francis Peabody³ in his monograph on "The Care of the Patient" said that "what is spoken of as a clinical picture is not just a photograph of a man sick in bed; it is an impressionistic painting of the patient surrounded by his home, his work, his relatives, his friends, his joys, sorrows, hopes and fears. . . . Everybody, sick or well, is affected in one way or another, consciously or subconsciously, by the material and spiritual forces that bear on his life, and especially to the sick such forces may act as powerful stimulants and depressants. . . . In all of your patients whose symptoms are of functional origin the whole problem of diagnosis and treatment depends on your insight into the patient's character and personal life, and in every case of organic disease there are complex interactions between the pathological processes and the intellectual processes which you must appreciate and consider if you would be a wise clinician."

THE UNDERLYING FACTOR

We have then reviewed the long list of somatic complaints, those outward physical signs of an inward spiritual restlessness, which bring the patient to the doctor's office, and we have by

3. Peabody, Francis W.: *Doctor and Patient*, New York, Macmillan Company, 1930, pp. 27-57.

patient questioning and sympathetic listening constructed the patient's background and environment and his reactive processes. What now in this typical psychoneurotic group are the underlying psychopathic factors? About 75 per cent of the patients are women and the problems are therefore predominantly feminine problems. Men are more apt to recognize the underlying maladjustment or mental conflict as a cause of the trouble and either meet the issue or rationalize their feelings. Recognizing the cause as psychic, the man is also less apt to seek medical advice than is his wife for her supposedly physical complaints. Furthermore, with his work and his greater freedom he is able to compensate better for the lack of mental harmony.

Among the men the anxiety states and depressive neuroses account for about 40 per cent of the cases, while only 12 per cent of the women will be found to fall in this group. Without a psychoanalytic survey one is seldom able to find a cause for these usually severe and well established neuroses. The difficulty is that we are dealing with a personality, with a mental state, that has become pretty well fixed. The anxiety state may often be traced to childhood environment or experiences, even to anxieties never consciously experienced; but the emotional state has been "displaced" from the original object and transferred to other objects, or anxiety has in fact become a habit of thought. Thus, for example, the child whose tranquillity and security have been threatened by marital discord of the parents grows up into a person surrounded with thick banks of gloom who, although he recognizes that he is no longer dependent on his parents for happiness and security, still approaches each new episode of life with fear. To treat these individuals properly, one must completely rebuild the personality, a task calling for a skilful psychiatrist.

INADEQUATE EQUIPMENT

About the same percentage of the male cases and about half of the females will fall in that large group characterized as being constitutionally inadequate. A few of these by careful psychiatric study could probably be more accurately classified, but most of them seem simply to belong to that group with inadequate equipment to meet and handle the problems of everyday life. The trouble may often be traced back to hereditary instability, to poor childhood environment or to early psychic trauma, but in any event the adult psyche is a weak vessel. One might well say that these patients are like boats which are safe and comfortable as long as they stay in the sheltered waters of a harbor but which will founder if subjected to the buffeting of even an ordinary sea outside. It is this type of man who was "shell shocked" in the World War (as the term was then loosely used). In this group we find the woman for whom the

ordinary obligations of married life are too great a burden and who often escapes to her physical ailments as a subconscious excuse for her failure to "make good." It is this type of patient in whom the will to get well is often feeble because health means again going out into a world that is already too great a challenge, whereas illness is a not uncomfortable refuge.

Many of these states may also be traced to childhood. It is Adler's belief that all psychoneuroses are based on some phase of an individual's expression of his ego, in a striving for power. Thwarting of this instinct then in the formative years may be the basis for the present trouble. Frustration breeds lack of confidence and a noncooperative mental state. On the other hand, too great coddling is detrimental and many adult neuroses can be traced to lack of mental discipline. It is to be hoped that our advocates of progressive education will not let their enthusiasm carry the movement so far as to remove all the drudgery from school work. There is great virtue in doing well an unpleasant and uninteresting task, the only rewards for which are the escape from a penalty and a satisfaction with a job well done—again an expression of power.

THOSE WHO NEVER GROW UP

In this group of constitutionally inadequate individuals are those who never grow up. These people with their ingenuousness and childlike ways are often most attractive but they are awfully hard to live with. After all, there is not a Santa Claus and the dolls of the nursery do not present the problems real children do. One must in adult life face and adjust oneself to reality. These individuals usually fail and drug addicts, those who seek the comforting anesthesia of alcohol or drugs to escape from a reality they would not face. In fact in this group we find, I think, most of the disagreeable and pathetic individuals of society—introverts retreating from an alien world, nagging women and fault finding men, showing in their attitudes evidence of a transference of disappointment and hatred because of thwarted desires and ambitions, reformers who finding themselves too small or too helpless in an unfriendly world try to make it over to fit themselves. Many mental states can therefore be explained on the very simple basis of this constitutional inadequacy.

In the performance of the physical tasks called for in our daily routine we expect to have the necessary strength and reserve to accomplish them. The normal youth expects and enjoys the physical training and exertion to make this possible and is ashamed to be called a physical weakling. Our daily routine calls also for mental stamina and reserve. If

these have not been developed we cannot meet the demands made on us and we not only fail but create within ourselves a mental complex as we struggle with our inadequacy.

A large number of women and a smaller number of the men (24 per cent and 8 per cent respectively in the series studied) have neuroses based on maladjustment to marital and home life. It is with considerable temerity that I approach the subject of marriage, but as one reviews intimately the details of this relationship in the lives of patients and of friends one cannot but reach the conclusion that American marriage often results in some bizarre situations. The sexual instinct, the desire for a mate, is simple, fundamental and primitive. But marriage instead of being the solution of a social and individual problem actually creates problems where none existed before—and this is true even where such obvious harassments as family dissension, financial worries, differences of social and educational background, and clashes of personality are nonexistent. It is pertinent to point out the factors that are so often causes of mental conflict and maladjustment.

THE PLEDGE AT MARRIAGE

In the first place the pledge at the time of marriage with its "till death do us part" is too irrevocable in spirit. In spite of the ease of divorce, an individual with a highly developed conscience or with a high sense of consideration for others (the type of individual that gets into mental quagmires), this type of person has a strong feeling of marital obligation and will not desert even an unworthy mate. On the other hand the unworthy mate often makes up her mind that she is not going to be deserted and creates a situation that is most difficult of solution. From the medical point of view, divorce as an escape from an aggravating situation should be not only legally easy and fair but also without social stigma.

In addition to the finality of marriage, which mentally depresses many individuals, there is often demanded a complete submergence of personality which obliterates them as individuals. The I becomes We. Old friends are lost, old associations, even old habits, are given up in the interest of marriage. In other words, the individual is made over to fit the relationship instead of the individual finding a relationship that fits him—a situation calling for adjustments which are often the cause of mental conflict. In women the failure to find in marriage the emotional outlet that was expected, the realization that marriage is a business and social partnership rather than an adventure in romance, often results in a repression neurosis. In men, on the other hand, the domination and surveillance by their wives, more complete than anything experienced under parental supervision, breeds a conflict with instinctive desires

that sometimes results in periodic debauchery, in alcoholism or in some other form of psychic escape. The actions of American men at a convention away from home and without their wives are pathetic evidence of the restraints and inhibitions under which they regularly live.

A PARADOXICAL SITUATION

Not only may marital conflict cause somatic disorders but the converse is also true. The possibility of chronic ill health in one's partner may in accordance with the marriage vows be accepted as part of the contract, but it may also result in frustration and resentment. Another source of maladjustment is seen in women who prior to marriage have held responsible and interesting positions and who after marriage find themselves alone and idle most of the day or at best engaged in petty household routine.

In short, from the psychiatric point of view the problems of marriage are problems of the emotions or of the conflict of the emotions with experience. Furthermore, it seems that those who emotionally need marriage the most, those whose intensity of feeling calls for such outlet, are the individuals most likely to present these problems. The cause of this paradoxical situation lies, I believe, in a misconception of the place of marriage in the psychic pattern.

Sentiments may be said to be "organizations of the instinctive tendencies and consequently of the emotions around various objects." There is a need in life for a dominant central sentiment, "a star to hitch one's wagon to." This central sentiment should be invulnerably entrenched within oneself. The integrity of marriage is anything but invulnerable, its fate is shared between two individuals. Marriage should be a means to an end instead of an end in itself. It cannot be the basis for a satisfactory dominant central sentiment. If all of this were recognized, if marriage and the sentiments built around marriage were only subordinated to more stable instruments, if in other words marriage demanded less of its victims and less were demanded of it, it would fit better into our psychic pattern.

Although in a larger sense all marriage problems are sexual problems, physical sexual incompatibility as a cause of affective disorders is relatively unimportant. In women loss of libido or actual frigidity is often a symptom of a psychologic conflict. Sexual habits and reactions should be studied in each case and the cause of abnormalities determined if possible. It should be remembered that impotence in the male and frigidity in the female are practically always psychic rather than physical in origin. For this reason they are most difficult to handle and after a psychoanalytic house cleaning glandular therapy, for its suggestive as well as for its actual endocrine replacement value, is indicated.

One hears much of the problem of sex inhibitions in the unmarried. I feel that it is an over-emphasized problem. In the first place there is in these days more sexual freedom in the single state than there is for those under the restraint of marriage. In the second place it is perfectly possible for a person to get along without sexual intercourse if he has some other interests in life and if overzealous friends will refrain from meddling in his love life. Much unhappiness and sexual unrest are caused by our American overemphasis on sex. We are the most sex-conscious people in the world, and what should be instinctive and emotionally spontaneous becomes an artificially produced obsession. In spite of this, sex problems and in fact problems of any sort are less common among the unmarried than among the married.

BUSINESS WORRIES

Of greater significance among psychoneurotic men than marriage and sex is business. (Worry or dissatisfaction in business will account for about 25 per cent of the cases.) The changing social order has created troublous economic situations which are causing more unhappiness than did the old order which they are trying to change. It should be remembered that in these cases it is not long hours and hard work that cause the mental perturbation but rather the factors of fear and uncertainty and indecision which nag at the individual and interfere with his normal mental rhythm. As in marriage, there is sometimes the factor of frustration and disillusionment as a man finds his way to achievement blocked or the validity of his ideals questioned. There are, of course, only two solutions to the problem, and from the psychiatric point of view it is immaterial which road is taken. The patient must adjust himself to his environment, accept the inevitable or get into another line of work.

It is of interest that grief, such as over the loss of husband or child or over some family calamity, accounts for the disturbed mental state in some of the women (8 per cent) but in men is rare as a neurogenic factor. The grief complex is, of course, simply a lack of adjustment to a loss, sometimes due to a pitiful lack of other sentiments and interests, and sometimes to a morose enjoyment of the emotion of sorrow or of the sympathy that comes in its train.

Two other etiologic factors apt to be seen exclusively in women are conflicts due to family complications (other than marital) and nervous exhaustion due to mental and physical trauma. Because there is so little that can be done for these groups in a remedial way, it is fortunate that the two classes are small. Filial obligations are often a depressing problem, but as long as one has a conscience there is no escape; as for trauma, it leaves scars that cannot be obliterated.

The menopause is blamed for many of the depressive neuroses and in this woman has no monopoly. A male menopause, with mental and physical symptoms, is now described. As stated before, I do not believe this is endocrine in origin except that the somatic symptoms due to the endocrine dysfunction are aggravating factors in precipitating a mental breakdown. Sometimes there is a constitutional instability and inadequacy which will not stand the strain of any increased physical burden. Also it seems that often with the approach of the menopause the woman realizes keenly the end of her reproductive period and the approach of old age, in which because of menopausal symptoms the infirmities of age are emphasized. In balancing the books she realizes that the romance of childhood, young womanhood and motherhood is over. Often she has nothing left but the companionship of an aging and often unfaithful spouse and she feels the world closing in around her. In the neuroses and hysterias of this period of life in both men and women, one is reminded of the final struggle of the fish before being gathered into the net. It is my impression that this psychoneurosis of the menopause is much more common in married than in single women, though both, of course, have the physical symptoms. Fortunately this is usually a passing phase. In the normal individual, mental adjustments are made and middle and old age may prove to be the most serene and happy periods of life.

CASE HISTORIES

A few case histories will illustrate the neurogenic backgrounds I have been discussing and will help visualize and emphasize the problems:

As an example of the anxiety neuroses there is the case of a young Jew, manager of a small store. He consulted a physician because of chronic indigestion from which he had suffered for years. The manifestation of this had been heartburn, eructation of gas, bloating and constipation. Several weeks before coming in he had fainted several times in one evening and on three occasions since that time. At other times he had chills which had lasted from fifteen to thirty minutes. There had also recently been considerable dizziness. It developed that he had been under medical observation on numerous occasions and that all investigations, including gastrointestinal roentgenograms, had been negative except for evidence of a hypermotility of the intestinal tract. Cutaneous tests had revealed sensitivity to several foods, but elimination of these foods from his diet had failed to give any relief. A gastric analysis, electrocardiogram and basal metabolic rating had all been negative. This young man was found to work long and hard at his business, he took no exercise and he had no hobbies. He roomed with two business associates and said that their conversation in their off hours was largely about their business. A repetition of the gastrointestinal studies and of the other laboratory procedures failed to reveal evidence of any organic disease. He was given symptomatic treatment and obtained enough relief to warrant his returning every few days for adjustment of his routine. What this individual needed, of course, was a complete change of personality with a resulting interest in activities, both physical and

mental, outside of his job, and better balance in his application to his work.

Another case of the same type was that of a 35 year old seaman who complained of nervousness, arthritic pains, a postnasal discharge, indigestion, and worry over the firmness of an old hernial scar. A number of years before he had had a gonorrhea, which had apparently been thoroughly and effectively treated, and at another time he had been told that he had tuberculosis. In spite of repeatedly negative physical examinations he worried a great deal about both of these possible conditions. His mental state was further disturbed by a recent marriage and subsequent separation. He was advised to try to forget his physical symptoms, to settle his marital mixup, to seek a change of work and environment and finally, in the event of the need for medical attention, to seek the services of a psychiatrist rather than of a urologist.

The 38 year old wife of a government official, with her many symptoms and negative physical examinations, is a good example of the tremendous amount of ground that can be covered in a thorough study of one of these cases. When first seen her complaints were malaise and fatigability, anorexia, nausea and vague abdominal distress. She related that this was a recurrence of a symptom complex which had occurred several times previously and that complete examinations at each time had failed to reveal any organic disease. While she was under observation there were a number of interesting clinical episodes. She intermittently had an afternoon elevation of temperature, there was at times a severe neuralgic pain in the upper part of the back, at other times there was an unexplained discomfort between the costal margin and the crest of the ilium on the right side, at another time she developed a temporomandibular synovitis, later she developed a severe urticarial rash accompanied by an axillary and inguinal adenitis which was unexplained and which subsided spontaneously, and intermittently she had a "black tongue." Hers was one of the case which always keeps the attending physician worrying over the possibility of missing some hidden condition, particularly in view of the fact that there was never any demonstrable psychopathic factor which could explain her condition on a neurogenic basis. She was happily married, there were no financial worries, and she often made the statement that she had everything to live for and desired nothing as much as she desired getting well so that she could enjoy life. The patient was studied from every possible angle, and almost every known test was carried out on her in order to rule out possibilities in differential diagnosis. She has been treated by various physicians, both as an ambulatory patient and in sanatoriums, and is now in a mental hospital with an established diagnosis of constitutional inadequacy. One of the psychiatrists who had had her under observation for some time explains her mental condition on this basis: Her premarital life was unsatisfactory and somewhat unhappy. She rather pictured married life as an ideal state where she would be relieved of all disagreeable responsibilities and distasteful duties, but as time passed and she failed to realize these expectations her unformulated and unconscious hopes began to fall down about her, leading at first to anxiety and later to depression. He pointed out that behind all this, of course, is a lack of training and preparation for normal living which left her with a rather infantile personality.

In the 32 year old wife of an automobile salesman, we see an example of the vague somatic complaints that may be traced to marital incompatibility. She first consulted me with a complaint of periods of lassitude which she had had intermittently since the birth of her first child two and one-half years before, the condition being worse since the birth of the second child three months before. She suspected that

her trouble might be due to hypothyroidism, for which she had been treated in the past, and a basal metabolic test revealed a rate of minus 19. Thyroid medication, however, failed to relieve her symptoms. It was rather typical of this woman that although she was in essentially good health and had before her marriage been active in sports she now took no exercise, had no hobbies and was inactive socially, although she said she still was gregarious in her tendencies. In other words, she seemed to have lost all ambition and interest in life. Advice with regard to the need for exercise and a general change in her habits brought no results and finally in a discussion of sexual relationships where she admitted loss of libido she stated frankly that she had never really been in love with her husband and was now bored with him and with married life. Divorce was discussed quite frankly with both the patient and her husband, and it is interesting that, although no definite step was taken in this direction, dragging the problem out into the open and offering a way out was in itself enough to bring at least partial relief from the somatic complaints.

A young woman who had been married for only one year was referred to us by her mother because of malaise and loss of weight. She had no other complaints and her physical examination was entirely negative. It was only on the third visit and after considerable insistence on the part of the examiner that she admitted unhappiness in her marriage due to financial and social restrictions. On the next visit and after further questioning it developed that her marriage had been precipitated because of a supposed pregnancy and that she really wished to escape from a situation into which she had been forced. As in the preceding case, as soon as a solution of the problem was presented in the form of separation and subsequent divorce the patient was relieved of her malaise and immediately started to regain the lost weight.

That psychoneurosis does not always result in loss of weight is shown by the case of a woman of 48 who consulted me primarily because of overweight. Except for a mild indigestion there were no other complaints until at a later date the patient said that she had for some time felt "bad all over," and the husband revealed a background of considerable marital incompatibility and worry over finances. It is possible that overeating either as a manifestation of nervous instability or as an effort to satisfy an unexplained craving may be a not infrequent manifestation of psychoneurosis.

A housewife of 27, in very moderate circumstances, was seen one night complaining of severe pain in the right lower quadrant with diarrhea and vomiting. She had had several similar attacks during the previous nine months. There was a slight elevation of temperature and there was sufficient tenderness and spasm in the right lower quadrant to justify an appendectomy, in spite of a normal white count. The appendix, however, was obviously not the cause of the trouble and a small ovarian cyst, which might have been causing some discomfort, was removed. This patient had a normal convalescence but on the day that she was discharged to her home she had a nervous chill and again a slight elevation of temperature. Over the succeeding several weeks there were recurrent attacks of nausea accompanied by nervousness, tremor and chilling. On intensive questioning it was revealed that besides her own children she had a stepson who had recently come to live with them. He was epileptic and apparently also had some mental deterioration which had resulted in a fear of him by the patient and dreams at night about the boy's attacks. I felt, of course, that this woman had had an unnecessary operation which might have been avoided if beforehand more could have been known about the family situation.

A not unattractive Jewess of 39 was referred to me for a heart examination because of symptoms of palpitation.

tation with exertion and excitement, shortness of breath with exertion, precordial pain, and occasional spells of faintness. Other somatic complaints were a pain in the right flank and back, intestinal indigestion, and a mild productive morning cough. A cardiovascular examination, including an electrocardiogram, was entirely negative. The woman was the wife of the proprietor of a store in which, up to two years before, she had worked as a cashier, at which time she had had a nervous breakdown. Her present attack had been preceded by hard work at the store, worry over the building of a home, and some conflict over some of her husband's family. She volunteered the information that before marriage she had lived in a large Eastern city where she had been in charge of a show room in a woman's clothing store with thirty models under her and where there was always laughter and life and activity. Marriage had meant for her giving this all up, because at first her husband objected to her working and she was left sitting alone all day in an apartment twiddling her thumbs and smoking cigarettes. The greatest excitement of the day was going out to dinner with her husband. Here, of course, is an example of a woman who did not have sufficient background to build a life of her own, who was unable to adjust herself to marriage, and who was annoyed and disturbed by the nagging pettiness of the life she was forced to lead. Such mental conflict and maladjustment resulted in sympathetic nervous system instability, which of course explained all of the somatic complaints.

It is quite obvious that, quoting again from Francis Peabody, "What is spoken of as a clinical picture is not just a photograph of a man sick in bed; it is an impressionistic painting of the patient surrounded by his home, his work, his relatives, his friends, his joys, sorrows, hopes and fears."

TREATMENT

Somatic complaints—indigestion, cardiovascular disorders, malaise, neuralgia and the rest—originate in the psychoneuroses usually through disturbance of the so appropriately called sympathetic nervous system. And, conversely, in some instances a minor physical disorder dragging on an unstable nervous system precipitates a psychoneurosis. In either event patient and sympathetic treatment of these physical disorders is most essential. It is apropos to say here that, in the handling of these cases from both the mental and the physical angle, it is necessary that time be given generously to each patient. I am reminded of the anecdote of one of our great clinicians who was seeing a case in consultation in a small town near Baltimore. One of the doctors with him whispered that if he hurried he could catch a certain train back to the city. The consultant replied that they could afford to miss the train but that above all things they could not afford to be in a hurry.

This is certainly the attitude that one must take in attempting to treat these contrary and difficult cases, and in addition to this there is no condition that I know of where scrupulous attention to the details of treatment is more important. There is a temptation to give placebos and to meet each new ailment with a new prescription as the patient expects the physician

to do. There is, however, more constructive benefit in giving to the patient in addition to the necessary medication a little insight into the cause of the somatic complaint, and a little encouragement to subordinate the symptoms if they are, as is common, too engrossing an interest or if the threshold to pain is too low or the tolerance poorly developed.

Treatment of the basic neurosis may take one of several forms. Suggestion with its placebos for the soma and hypnotism for the psyche has been abandoned as being of little permanent value. Persuasion alone is effectual because it calls for constant application. Persuasion is a crutch on which the patient leans and without which he is again helpless. It cannot be dispensed from the doctor's office. It is used in sanatorium care but is of value only as a temporary expedient. Incidentally, since the acceptance of persuasive guidance by the patient is based on respect or even affection for the physician dispensing it, since its success is dependent on continuous faith in another person, it is wrong in principle, because what the patient needs is self reliance and self discipline. Compulsion, were it possible, might in many cases be the therapeutic answer. The family and friends of patients, and in fact society at large, would, however, hardly support a regimen of severity and disciplinary routine. Yet circumstances sometimes accomplish this when the neurotic patient receiving sympathetic and expensive sanatorium care loses his money, is faced by an unsympathetic world and is in consequence suddenly cured. One sees less psychoneurosis among men than among women partly because economic compulsion forces the man to keep his emotions under control, whereas his wife, better protected and with some one else to do the worrying, gives way to hers. I heard recently a story of a prosperous and neurotic patient who insisted on an interview with a prominent psychiatrist. The psychiatrist was just ready to leave for a summer vacation but under the insistence of the patient and his family was persuaded to delay his departure. The patient arrived and was asked to tell his story. As he recited his woes the mountains and streams were, I suppose, beckoning his doctor listener and when the story was finished he looked at the patient and said bluntly "Well, what of it?" The patient under the sting of this rebuff straightened out his mental processes and needed no further treatment. This was an unusual situation and an unusual patient; nevertheless the story has its point, and I think we may be justly accused of sometimes encouraging with too much sympathy some of the psychoneurotic states.

The treatment of choice is psychoanalysis, with the patient being made to understand himself, to appreciate the mechanism of the inter-

relation of his mental conflicts and his physical distress, to minimize his symptoms through this realization of their significance, and to recognize his limitations. As mentioned before, the will to get well is indispensable to recovery and the hopeless cases are those in which a life of invalidism is easier and more interesting than a battle for existence with inadequate mental equipment.

THE WEIR MITCHELL REGIMEN

When the psychoneurosis is completely disabling, the old Weir Mitchell treatment is often most effective. It is sound in theory and efficient in its application. The patient is, after careful clinical study, put in an institution, preferably a quiet convalescent or nursing home. He is completely isolated from his old environment and an effort is made to start him off anew, physically and psychically. An efficient and sympathetic nurse is essential. Except for the visits of the doctor and the nurse he is completely shut off from the outside world. He is not even allowed to receive or to write letters. He is put to bed and placed on a semistarvation diet. After a few days, if there is no serious gastrointestinal disorder, the diet is rapidly increased and the patient's first new interest is perhaps in his food and in his increase in weight. Massage and hydrotherapy, which at first are sedative in character but later more vigorous, are part of the regimen, and the visit of the masseur comes as an added diversion and interest. Later, occupational therapy of some simple type is added to afford some physical activity and training in concentration. As the patient improves he is gradually allowed to extend his activities, to venture out for short walks, to come again in contact with the world. The role of the physician through all this is that of the master whose word is law but who, with encouragement, stands ready to help the patient find himself and by his professional skill to relieve the physical discomforts. What is needed in the attending physician is not a highly specialized knowledge of psychiatry or of any of the other specialties but rather a breadth of medical vision and skill that will enable him to make the patient comfortable. The physician should have a large fund of patience and compassion and common sense so that he can establish contact with the patient and win his confidence and, finally, should have the ability to call for and profit through help from consulting specialists when such aid is indicated.

The unfortunate part of the Weir Mitchell regimen is that it is possible only for the well-to-do; but the basic principles may be used generally. For example, even a clinic patient can arrange for rest in the quiet of her room for a period each day; she can resort to the bathtub for modified hydrotherapy; she can get a

taste of comparative isolation by visiting the home of some unmarried or childless friend once a week; she can test the value of occupational therapy by developing a hobby, and she can, of course, follow the required dietary regimen. If meanwhile the somatic complaints are adequately treated and the doctor takes the patient into his confidence and makes her understand the rationale of the procedure, the results may be most encouraging.

PSYCHOTHERAPY

Concurrently with the physical routine of such treatment there must be carried on a reeducation in mental processes—and sometimes one has to revamp completely the patient's point of view and his objectives if one is to have any more than temporary relief. The first requirement is complete insight by the patient into the working of his own instincts, emotions and sentiments, and an understanding of his conflicts and maladjustments. The next step is the working out of a practical solution of the problems presented. The patient must be made to understand that it is not so much the harassment of his environment or of the situation in which he finds himself that causes his mental turmoil as it is his own failure to take his bearings, study his charts, lay out a course and get under way. It is indecision and uncertainty as to what is really wanted or as to what one should do that causes the conflict, rather than the disagreeable factors themselves. For example, one must often explain to a patient whose maladjustment is due to marital conflict that from the medical point of view it is immaterial whether he gets a divorce or decides to accept the situation as inevitable, but one or the other he must do.

Some of these people must be taught to acquire a philosophy of life which Osler¹ summed up in the Latin word "aequanimitas." By this he meant schooling oneself not to expect too much of life or of the people among whom one lives, learning that "we aim at the unattainable and must be content with finding broken pieces," accepting courageously disappointment and defeat and joyously fighting on, with only the acquisition of quiet wisdom as one's reward. Carlyle said of Teufelsdröckh that after a period of "ragings and despairings" over a soul tragedy "the first mad paroxysm past . . . he collected his dismembered philosophies and buttoned himself together." Some of our psychoneurotic patients must be told quite bluntly to do just that. And, to quote still further, they may well be asked "What is it . . . thou has been fretting and fuming and lamenting and self-tormenting on account of? Is it not because thou art not happy? Because thou (sweet gentleman) art not sufficiently honored, nourished, soft-bedded and lovingly cared for?"

¹ Osler, William: *Aequanimitas*, with Other Addresses, Philadelphia, P. Blakiston's Son & Co., 1930.

Foolish soul! What act of Legislature was there that thou should be happy? A little while ago thou had no right to be at all."

In the practical working out of this buttoning of oneself together, the cultivation of hobbies is most helpful. It is often difficult to find anything outside of work and family life that has ever intrigued these individuals, and in the slough of despond in which one finds them it is often next to impossible to create an interest. However, a study of the individual's mental and physical capacities should enable one to prescribe, as one would a medicine, some activity for rather serious cultivation. It is well to have two hobbies, an outdoor one involving physical exertion and an indoor one calling for some mental concentration or manual dexterity. It makes little difference what one turns to, it may be working in the garden and making a serious study of bridge, or it may be fishing and collecting stamps. The important thing is to develop some variety in the psychic diet.

PROPHYLAXIS

One should not close a discussion such as this without some general considerations of the causes of and prophylaxis against such psychic failures as we have been considering. After all it is inevitable that in this business of development and of achievement or even of mere existence we should encounter obstacles and problems and unpleasant as well as pleasant experiences. A normal response to this is a strengthening of moral fiber, mental stability and stamina. The ships that founder have some defect in their construction. Says Macfie Campbell,⁵ apropos of this, "For the somatic functions to work, energy must be readily available and there must be reserves so that work can proceed smoothly and emergencies be met. Psyche too must have reserves, must have her store always readily available. It is too late, when an emergency is met, to seek for external resources. A richly stored mind is not a question of original endowment; although native ability is important it is the result of systematic industry, of careful utilization of time, of the utilization of opportunity. If, when serious demands are made, the necessary resources are not available, habits have not been formed, knowledge is absent, a code of conduct is not part of their equipment—inadequacy, inferiority, distress are the result." Let leisure time, he urges, be utilized in part to stimulate and enrich one's thought and contribute to one's philosophy of life. His idea may be summed up in the admonition "Develop your background."

I have spoken of the need for a dominant central sentiment. With such a sentiment there is no conflict or indecision as situations arise.

But, as has often been pointed out by McDougall and others, this sentiment must be organized around something that cannot be lost, preferably around an ideal or rule of personal conduct. Thus one may develop the impregnable armor of self sufficiency and, though money, position, family, even reputation is lost, be invulnerable. The rules of conduct and a code of living can never be taken away and need never be lost. Strength and stability of character have these as a backlog.

THE ART OF LIVING

Having thus a strong background and a guiding motive, what now does the healthy mind seek? What is the goal? I think we normally change our course as we grow and taste of life. In early youth one usually has the urge or even the compulsion to do something worth while, to produce. With Carlyle's Teufelsdröckh, youth cries out "were it but the pitifulest infinitesimal fraction of a product, produce it in God's name, 'tis the utmost thou hast in thee; out with it then." Then, as youthful ardor cools, the gregarious instinct is likely to assert itself and the individual craves popularity and recognition. The herd instinct is strong. And finally as disappointments temper enthusiasm, as experience shows the instability of faith and dependence on others, the ultimate goal is personal happiness and independence. It has been said that true art consists in living the way you want to live and throwing aside if you wish the ways of your neighbors. And I think it is the psychological art because it makes for peace of mind rather than for conflict and maladjustment.

It might be objected that, if all of us selfishly followed this rule of conduct, civilization would come to a standstill; but I think not. Some men are immoral and evil because they want to be, but men are also moral and honest because for them therein lies happiness. We would still have the industrious and the lazy, the economical and the extravagant, the pacifist and the militarist. In spite of utter freedom of thought and action we would still have social reformers and uplifters. In fact, the world would be about as it is now except that there would be well ordered mental objectives and a recognized art of living.

For you who are about to go out to diagnose and treat the ills of mankind, it is immaterial whether you accept the psychiatric tenets of Janet or Freud or Jung, or whether in your philosophy you follow Nietzsche or James. It is essential, however, if you would be a wise physician and not merely a medical mechanic that you see in your patients more than just a bit of anatomic and physiologic machinery, and stand ready to mend their backgrounds, their dominating central sentiments, their philosophies of life and their objectives.

1400 Medico-Dental Building.

Comments and Reviews

CLINICAL SENSE AND CLINICAL SCIENCE

Condensed from an article by Dr. John A. Ryle, regius professor of physic in the University of Cambridge, in the Lancet, May 13, 1939.

We have all admired in our friends or our chiefs the ability to arrive, without betraying the whole process, at wise and accurate decisions. This ability is shared by all of us in some degree, or else we are no physicians. Swift and wise decisions have a clear relationship especially to length of experience. Clinical sense is not innate or intuitive but a complex faculty built on prolonged training and exercise of the special senses, with a sound knowledge of pathologic possibilities. Observational ability and habit, a retentive memory and aptitude for sifting and correlating experience are the main ingredients of clinical sense.

Observational ability and the wit to interpret phenomena may, on occasion, lead to surprisingly prompt and exact judgments. With the clinician and the puzzling case it is not the single physical sign so much as the circumstances of the illness, the age and habitus and environmental conditions of the patient, the syndrome echoing syndromes encountered before, or even a single peculiar symptom or sign recalling the features of a single other case. These and an estimate of "the whole patient" and of his reactions to his illness may tell more in diagnosis, prognosis and treatment than the most careful examination, more sometimes than all the details of a modern "complete investigation" with its attending expense and inconvenience to the patient. Such judgments cannot be called guesswork. They are the result of a discipline of the special senses, of an observational science differing only from the discipline and science of the laboratory worker in that the observations have not been set down in orderly protocols but lodged and stored in a busy mind. For the biologist's records and methods, the physician must constantly substitute his powers of memory and association. There are some stories of Sir William Gull's consultative triumphs, in which clinical sense and common sense prevailed where the wit or industry of others had been found wanting. A surgeon had a case of ununited fracture which was giving him concern and decided one day to waylay Gull and ask his advice on the case. Gull took a look at the man and said "Feed him on tomatoes"—nothing more. The instruction was obeyed and the fracture united. When asked later his reasons for this advice, he replied that the surgeon might know all about fractures but had failed to observe that the man had signs of scurvy.

Good clinical sense seems more rare today in the field of treatment than is the case with diagnosis. The urge to action, the over-reliance on surgery, the vaccine craze, the proprietary endocrine allurements, the blandishments of the advertising chemists all have helped to lead us astray. We must feel ashamed at times of the ready susceptibility of our profession to fads and crazes in treatment. Drugs doubtful and drugs inert, drugs unorthodox and even drugs dangerous are prescribed in vast quantities and often to the neglect of sensible management and regimen or a simple psychiatry. The man with good therapeutic sense avoids pitfalls and constantly adapts his physiotherapeutic and psychotherapeutic measures to the individual case, orders a shave or a change of room at the appropriate moment in a case of long illness; knows when to give morphine and when to withhold it; when to transfuse or not transfuse; when to tease, to be jocular or sympathetic, when to exhort or scold. At the same time he keeps abreast of new advances. The oncoming generations are obsessed with treatments rather than trained and versed in Treatment. I am disturbed by a falling off in the quality and quantity, or in the diffusion of sound clinical sense, among those just referred to as "the oncoming generations." But the fault is ours and not theirs. We allow them to be embarrassed by "a crowd of scientific facts" and methods instead of teaching them their proper place and use.

What is wrong with medical education that it should, while multiplying diagnostic aids and instilling far more basic science than our fathers had, be failing in its cultivation of judgment and the faculty of perception from which judgment derives? We need not go far for the answer. The overcrowding of the curriculum and the multiplication of accessory diagnostic methods are not alone to blame. . . .

The inevitable subdivision of medicine into specialisms has broken the continuity of teaching. The value of the "general approach" to every case, whether to a patch of eczema, an enlarged prostate or an anxiety state, is in process of being forgotten. Investigation is tending to supersede and exclude instead of to supplement clinical appraisal. In his first three years the student observes and investigates too little; in his last three years, while learning to observe and investigate, he forgets his physiology and thinks too little. If we could set ourselves to the task of restoring clinical discipline to its proper place, we should go far to counteract wrong tendencies and to assist our inadequate revisions of the medical curriculum.

MEANING OF CLINICAL SCIENCE

Let us now pass from the discussion of "clinical sense" to a consideration of "clinical science."

The applications of physiology, pathology, immunology, chemistry, endoscopic technic and radiology in medicine have conferred inestimable benefits, but they have also added embarrassments and have inhibited observational precision. They have hampered the orderly evolution of clinical sense where they might have enhanced it. They have made doctors more scientific in their methods and less so in their judgments. Concurrently with these disturbing evolutionary changes we welcome today the advent of a new branch of biologic inquiry which may be called clinical science. I cannot do better than quote a part of Sir Thomas Lewis's definition:

This science [he says] seeks by observation and otherwise to define diseases as they occur in man; it attempts to understand these diseases and their many manifestations, and here especially makes use of the experimental method. It makes definite experiments upon disease and watches the effects of experiment conducted by injuries however they arise; it culls, or actually creates and uses physiological and pathological knowledge immediately related and applicable to the diseases studied.

How can clinical science be fostered? Clinical science can be advanced wherever men of appropriate foresight and training have the time, the opportunity and the material within their reach. Sir James Mackenzie advanced clinical science in the course of a busy general practice. Men primarily engaged in practice or teaching will still make their contributions from time to time. The teaching hospitals and the professional units will make their contributions and play a useful part as training grounds for new recruits to the whole-time service of academic medicine; of necessity, however, they combine much undergraduate teaching and hospital routine with their research activities, and so their present atmosphere is not wholly favorable to scientific advancement. It would be a grave mistake for the disciples of clinical science to withdraw themselves too much into their own laboratories or to establish research institutions which would work independently of existing hospitals and university departments.

The interchange of thought and discussion of problems between the clinical scientist and the practicing physician and his assistants is one of the most hopeful developments of these innovations. The interchange of thought and partition of problems with other biologic scientists is as important. The clinical scientists must have beds of his own, not a large number, but he should be willing to confer on cases with his colleagues of the honorary staff, to stimulate their subordinates by his ideas and activities

and, while nursing his own interest, to become an active member of the larger hospital family.

We may have to accept that his scientific preoccupation with his problems entails a limitation of his clinical sense. Clinical sense is born partly of long and varied association with sick men, women and children, and partly of the very nature of that relationship. However separate a disease process may be, it tends to present in different ways and to have different effects in individuals. The physician learns more clinical sense, as a rule, from his private patients than from his hospital cases. He also acquires methods of approach and management which are sometimes of particular value in clinical assessments and are, on the whole, less easily acquired by the institutional research worker. Let us accept, however, that the clinical scientist is concerned rather with processes than with persons, and that his study of processes is not necessarily hampered, as the task of the physician would be, by limiting his view.

In the selection of research personnel, can we ask promising younger men to afford the time necessary for both disciplines—that which trains for clinical sense and that which trains for clinical science?

Lewis and his co-workers at University College Hospital have chiefly carried physiologic method into the clinical field. At Cambridge it is more likely that biochemistry will implement and direct our studies in the near future. But in neither place is it likely that one science alone will be called to the aid of the research physician. In neither place will other biologic methods remove the necessity for close observational method and training. I would beg of my friends in the metropolitan schools to search their hearts in the matter of medical education and to aim at so training their students that the coming generations of clinical scientists may still retain that "faculty of perception" which has been the hallmark of English medicine from the time of Sydenham.

Biologic scientists have sometimes looked askance at the work of the clinician. They do not appreciate the countless difficulties and interruptions to consecutive thought which the practice of medicine compels. The clinician, on the other hand, has sometimes belittled the work of the laboratory man who would assist him, knowing his lack of intimacy with the problems of personality, with the variability of diseases and symptoms, and with the severe limitations set by chance. Mistrust of this kind is foolish, and all occasion for it departs when there is close association between the practicing physician and the investigator within the same building. If the first and constant duty of the physician is to improve his clinical sense, his second is to preserve the closest possible contacts with all the related biologic sciences.

When science and practice work at close quarters, both must benefit.

In spite of all our difficulties the modern evolution of medicine is intensely interesting and full of promise. But to forget the discipline that assists the faculty of perception would be a calamity for which no other discipline could wholly compensate.

EDUCATION IN OBSTETRICS FOR GENERAL PRACTICE

Abstract of an article by Prof. W. Fletcher Shaw, of the University of Manchester, and president of the Royal College of Obstetricians and Gynecologists. Published in the British Medical Journal, Sept. 2, 1939.

Every teacher agrees that medical students must begin with a good general education and a sound knowledge of chemistry, physics and biology, to which must be added a good training in anatomy and physiology and, later, in pathology. In the last three years of his training the student must learn the general principles of the main clinical branches and how to apply the scientific knowledge he has previously acquired. He must be trained to elicit clinical facts by exact methods of examination and to piece these together. Thus he learns to observe, deduce and think. There can be no attempt to teach him all that is known in any one branch: that leads to confusion. Teachers must confine themselves to principles and should emphasize the interrelation between their own and other branches of medicine.

Given this sound foundation, the medical student is trained to remain a student all his life, capable of understanding and applying the advances which will be made and of adding to them himself. The young graduate is the product of the whole school and not of any one teacher, and it is only by cooperative effort of the whole teaching staff that a school fulfils its highest duty.

OBSTETRICS AND GENERAL MEDICAL TRAINING

Unlike other departments, obstetrics deals chiefly with physiology and for this reason alone would be worthy of a place in the curriculum. Another advantage is that in many schools obstetrics provides the only compulsory period for students of residence in the hospital. The main purpose of this is to teach the student obstetrics, but in a good hospital he will learn much more. Seeing the patients at all times of the day and night will develop his powers of observation; he will have impressed on him in the antepartum department the necessity of knowledge of general medicine and general surgery as well as of obstetrics; if he also attends domiciliary midwifery he will learn more of human nature and the handling of patients than in the whole of the rest of his medical course.

Some day we may waken to the great importance of this resident work and, by cooperation

with hospitals, make the last year of the course a resident one divided between medicine, surgery and obstetrics, with gynecology, and unburdened by the paralyzing effect of the final examination.

Pregnancy, labor and the puerperium are normal physiologic processes with a liability to develop varying degrees of abnormality. The whole effort of the antepartum department is to recognize and treat these abnormalities. Recognized beforehand and the appropriate measures decided on, few labors present any serious difficulty, while the same complications discovered only during the course of labor will often have a fatal termination for mother and child. In the antepartum department the student sees and examines large numbers of patients in normal health and learns to recognize any divergence from this state. Those who suffer from complaints during pregnancy he sees treated in that department or in the wards, and he soon realizes the value of early recognition and treatment. In the gynecologic department he learns that a large number of these patients suffer from troubles produced at childbirth and that many of these are preventable; while in the children's department he will see many victims of heredity, bad environment and obstetric miscalculations.

DIFFICULTIES IN TEACHING OBSTETRICS

One of the main difficulties, and one which can never be overcome, is that the onset and duration of labor cannot be controlled. It is therefore impossible to hold labor ward demonstrations at prearranged times, and the teaching on normal delivery must be left to junior members of the staff. Even the cases requiring major obstetric operations must, to a large extent, be left to the younger members. The professor of obstetrics is therefore in the same position for clinical teaching as would be the professor of surgery if the major part of his teaching was limited to emergencies.

Another difficulty which is rapidly disappearing is the misconception of the lay public that every qualified practitioner is a fully trained obstetrician capable of carrying out any obstetric operation. This leads to the worst evil of all—that the local reputation of a practitioner as an obstetrician depends chiefly on the speed with which he terminates his cases. The aim of the obstetric teacher is to turn out qualified practitioners who have a sound knowledge of normal midwifery. They must be able to recognize the abnormal and to deal with minor abnormalities. Unless they have resident postgraduate experience it is not their business to perform major obstetric operations. A further difficulty is the way in which gynecology has developed and the tendency for the surgeon to consider it a branch of general surgery divorced from obstetrics. These subjects can never be

divorced. They are indivisible and between them embrace the study of a group of organs in health and disease. A knowledge of general medicine is required as much as that of general surgery. No one can be a gynecologist who has not obstetric knowledge of physiologic changes in these organs; no one can be an obstetrician who has not gynecologic knowledge of the accidents and diseases to which they are heir.

Teaching facilities and hospital accommodation in obstetrics and gynecology have lagged far behind those of general medicine and surgery, and only in recent years has a demand been made that these should be adequate. While in some schools the hospital accommodation is still deficient, it is gradually being overcome. The facilities for teaching clinical obstetrics have greatly improved in the last few years. The student should understand, however, that the amount which can be taught him is limited and that this cannot include operative obstetrics.

As most gynecologic ailments date from a confinement or miscarriage, it is essential that this fact be taught along with obstetrics, as only thus can the student realize the remote effects of bad midwifery, which must be taken into consideration when deciding on any gynecologic operation. The teaching of operative gynecology is not part of a student's course.

CLINICAL WORK

Too much emphasis has been laid on didactic teaching. Students have not been left sufficiently to ferret out facts for themselves and so develop the most important gift of the medical practitioner—that of observation. But the pendulum swings too far when it is suggested that systematic lectures be abolished. In obstetrics, systematic lectures are essential. Unless the student has a sound knowledge of anatomy and physiology and of the mechanism of labor he can never understand what is then happening and so be able to recognize when the normal passes to the abnormal.

LIVING IN A MATERNITY HOSPITAL

The General Medical Council regulations require that each student shall live in a maternity hospital for two months, and this is the most valuable experience in his career. He lives in a midwifery atmosphere, hears cases discussed by the residents, sees his cases night or day and is not hurried from one department to another. During this time he must himself conduct twenty cases. This unfortunately tends to overestimate in the student's mind the importance of this part of labor, and the teacher must be ever vigilant to counteract the impression that the moment of birth is the only, or indeed the most important, part of obstetrics. Frequent attendance at the antepartum clinic should be insisted on. Here the student must learn abdominal palpation; to recognize con-

traction of the pelvis, especially in its minor degrees; to study the patient's general health, and to give advice on diet and general rules of life; and to realize the importance of regular examination of the urine and of taking the blood pressure. His labor cases should, if possible, be attended equally in the wards and in the patients' homes. The student must realize that labor starts with the first uterine contraction and that the obstetrician's knowledge and skill are called for more frequently before than when the child is actually coming over the perineum.

In the two months residence it is impossible for him to attend the same cases in the antepartum department and in the labor wards, but he should see his patient as soon as she is admitted and he should be allowed to examine her along with the house surgeon. From then until delivery the student should pay her frequent visits and be taught to recognize normal from abnormal contractions, advancement, termination, and the condition of the patient. In this way only will he learn that the use of forceps is not decided merely by the number of hours in labor and the desire of the patient and friends for its termination. In the puerperium he should pay daily visits and be taught to observe the progress of involution, signs of abnormality in the patient, state of the breasts, and progress of the baby. It is a wonderful opportunity to instil into him the necessity of observation.

In his first ten deliveries attended in the hospital labor wards he has learned to maintain scrupulous asepsis. With everything ready at hand in a modern hospital this is relatively easy. The remaining ten cases must be attended with an equally rigid asepsis but in much more difficult surroundings. With more thought and trouble the same degree of asepsis can be obtained, but the student has to realize what are the essentials on which he must concentrate. To the student the chief advantage of the district cases is the daily attendance during the puerperium. These visits should be made by the student alone and he should be encouraged to record daily all the essential points—temperature, pulse, lochia, involution, sleep, bowels, breasts, baby—and to report to a senior officer any divergence from normal. By bringing him into contact with patients and their families in their own homes he will get his first lesson in one of the most valuable and difficult arts—the tactful handling of patients.

GYNECOLOGY CANNOT BE DIVORCED

The teaching of clinical gynecology is much easier than the teaching of obstetrics. As in medicine and surgery the patients come to outpatient departments at regular hours and are admitted to wards and operated on on regular days. Classes therefore can be organized in outpatient departments, wards and operating

rooms. There is one important barrier to teaching. Generally, a medical or surgical case can be examined by a number of persons and, if the diagnosis is in doubt, can be examined time after time. Not so a gynecologic case. The number of examinations made in each is limited. The practitioner must be taught that one physical examination must suffice. This means that the history of the case must be taken very carefully and each point considered in relation to the others, so that the gynecologist must have in mind what conditions could produce these symptoms in a woman of that age and history. In other words, his physical examination must be a differential diagnosis between the possible causes. Without this careful digestion of the history, physical signs are of little value. It is therefore of prime importance that the student should have beds allotted to him, should take careful notes of each patient and should be taught to find the possible diagnosis before an examination is made.

During the whole course of gynecology, emphasis must be placed on the interrelationship of obstetrics and gynecology, especially on the fact that many of the conditions found in the gynecologic department date from a confinement or miscarriage and that many of these could have been avoided.
